- The risk of adverse effects of a glucocorticoid is dependent on the disease, comorbidities, patient, dose, and duration of therapy.
- The risk of adverse effects of low-dose glucocorticoids is generally overestimated.
- After local injection of a glucocorticoid, the risk of local bacterial infection is very low.
- Low to moderate doses of prednisolone during pregnancy appear to be safe.

Even though biologic drugs are increasingly being used, glucocorticoids are still anchor drugs in treatment strategies for patients with rheumatic disease. The first glucocorticoid to be isolated, in 1935, was the endogenous glucocorticoid hormone cortisone. It was synthesized in 1944 and subsequently became available for clinical use. In 1948, cortisone (at that time called compound E) was administered by the American physician Philip S. Hench to a 29-year-old woman with active rheumatoid arthritis (RA) of more than 4 years' duration. This nearly bedridden patient was able to walk after 3 days of treatment. Hench published this case of dramatic improvement in 1949[1] and, along with two colleagues, won the 1950 Nobel Prize in Physiology or Medicine. Later, chemical modification of endogenous steroids enabled production of synthetic glucocorticoids, some of which have proved to be effective anti-inflammatory and immunosuppressive substances with rapid effects.

When the wide array of potentially serious adverse effects became apparent in patients treated with supraphysiologic glucocorticoid dosages, enthusiasm for and use of glucocorticoids decreased. Nevertheless, they continued to be the cornerstone of therapy of many rheumatic disorders, including systemic lupus erythematosus (SLE), vasculitis, polymyalgia rheumatica, and myositis. In addition, the use of glucocorticoids in therapeutic strategies for patients with RA also has become generally accepted.[2] The estimated prevalence of the use of glucocorticoids in the general adult population in the United States for all medical indications is 1.2%; this percentage predominantly reflects chronic glucocorticoid use.[3]

Although knowledge about glucocorticoids has increased during the past several decades, much remains to be learned about the modes of actions of these drugs in rheumatic autoimmune disorders. It is hoped that the unraveling of these mechanisms eventually may lead to new applications of glucocorticoids or novel classes of therapy with fewer adverse effects, as well as to personalized medicine.[4]

## CHARACTERISTICS OF GLUCOCORTICOIDS

### Structure

The precursor molecule of all steroid hormones is cholesterol, which is also a building block for vitamin D, cell membranes, and cell organelles (Figure 60-1). Steroid hormones and cholesterol are characterized by a sterol skeleton consisting of three six-carbon hexane rings and one five-carbon pentane ring. The carbon atoms of this sterol nucleus are numbered in a specific sequence; the term *steroid* refers to this basic sterol nucleus (Figure 60-2). No *qualitative* differences have been noted between the glucocorticoid effects of endogenous cortisol and exogenously applied synthetic glucocorticoids because these effects are, except for higher doses, predominantly genomic (i.e., mediated through the glucocorticoid receptor).[5] However, *quantitative* differences have been identified. The potency and other biologic characteristics of the glucocorticoids depend on structural differences in the steroid configuration. In the 1950s, when more potent synthetic steroid hormones were developed by chemical modification of endogenous steroids, research revealed numerous structural features essential for specific biologic activities. For instance, the 17-hydroxy, 21-carbon steroid configuration (see Figure 60-2) is required for glucocorticoid activity through binding to the glucocorticoid receptor. The introduction of a double bond between the 1 and 2 positions of cortisol yields prednisolone, which has about four times more glucocorticoid activity than cortisol (Table 60-1). Addition of a six-methyl group to prednisolone yields methylprednisolone, which is about five times more potent than cortisol. All these glucocorticoids also have more or less a mineralocorticoid effect. However, the synthetic glucocorticoids triamcinolone and dexamethasone have negligible mineralocorticoid activity.

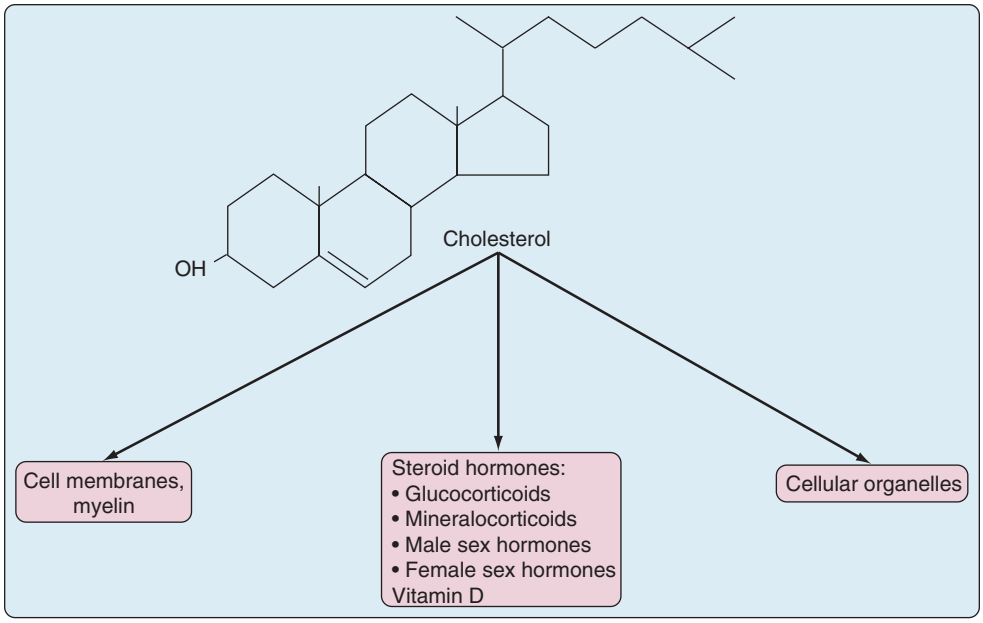

**Figure 60-1** Cholesterol as a building block for steroid hormones, vitamin D, and cell membranes and organelles.

**TABLE 60-1** Pharmacodynamics of Glucocorticoids Used in Rheumatology

| | Equivalent Glucocorticoid Dose (mg) | Relative Glucocorticoid Activity | Relative Mineralocorticoid Activity | Protein Binding | Half-Life in Plasma (hr) | Biologic Half-Life (hr) |
|---|---|---|---|---|---|---|
| **Short-Acting** | | | | | | |
| Cortisone | 25 | 0.8 | 0.8 | – | 0.5 | 8-12 |
| Cortisol | 20 | 1 | 1 | ++++ | 1.5-2 | 8-12 |
| **Intermediate-Acting** | | | | | | |
| Methylprednisolone | 4 | 5 | 0.5 | – | >3.5 | 18-36 |
| Prednisolone | 5 | 4 | 0.6 | ++ | 2.1-3.5 | 18-36 |
| Prednisone | 5 | 4 | 0.6 | +++ | 3.4-3.8 | 18-36 |
| Triamcinolone | 4 | 5 | 0 | ++ | 2->5 | 18-36 |
| **Long-Acting** | | | | | | |
| Dexamethasone | 0.75 | 20-30 | 0 | ++ | 3-4.5 | 36-54 |
| Betamethasone | 0.6 | 20-30 | 0 | ++ | 3-5 | 36-54 |

*Clinically; sodium and water retention, potassium depletion.
–, None; ++, high; +++, high to very high; ++++, very high.

## Classification

Steroid hormones can be classified on the basis of their main function into sex hormones (male and female), mineralocorticoids, and glucocorticoids (see Figure 60-1). Sex hormones are synthesized mainly in the gonads but also in the adrenal cortex. Mineralocorticoids and glucocorticoids are synthesized only in the adrenal cortex; the terms *corticosteroid* and *corticoid* for these hormones refer to the adrenal cortex. Some glucocorticoids also have a mineralocorticoid effect and vice versa. The main endogenous mineralocorticoid is aldosterone, and the main endogenous glucocorticoid is cortisol (hydrocortisone). Although the classification of corticoids into mineralocorticoids and glucocorticoids is not absolute (see later), it is more precise to use the term *glucocorticoid* than the term *corticosteroid* when referring to one of the glucocorticoid compounds.[6]

## Activation

Glucocorticoids with an 11-keto group, such as cortisone and prednisone, are prohormones that must be reduced in the liver to their 11-hydroxy configurations—cortisol and prednisolone, respectively—to become biologically active. For patients with severe liver disease, it is thus rational to prescribe prednisolone instead of prednisone. This formation of biologically active glucocorticoids from their inactive forms is promoted by the reductase action of the intra-cellular enzyme 11β-hydroxysteroid dehydroge-

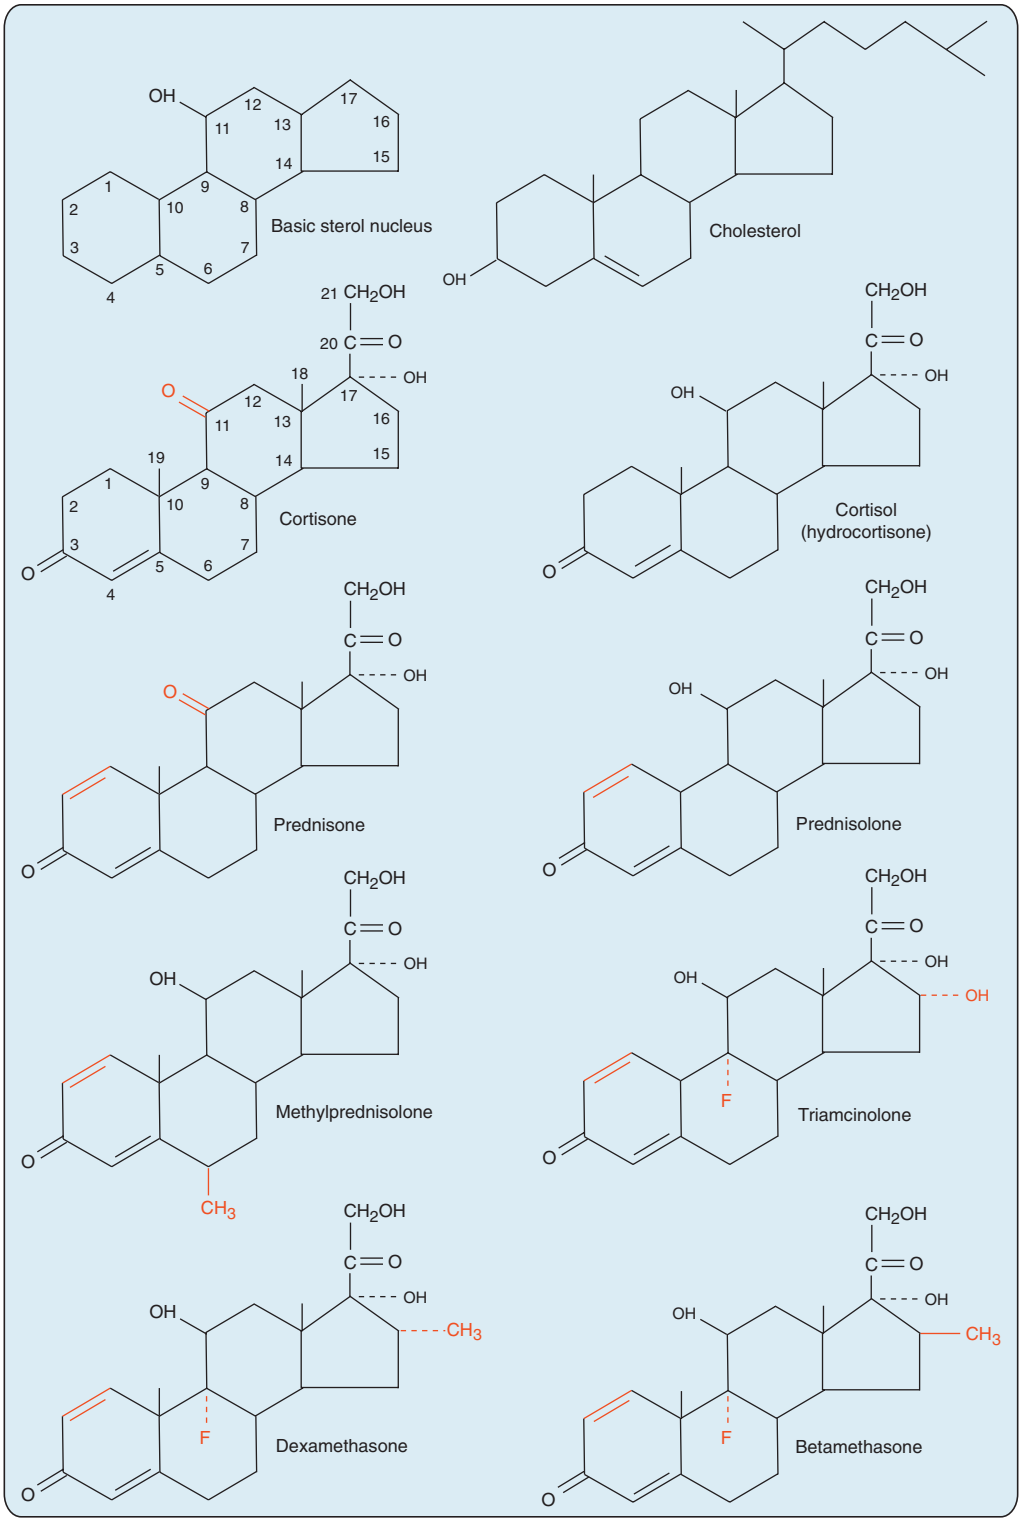

**Figure 60-2** Basic steroid configuration and structure of cholesterol and of natural and some synthetic glucocorticoids. Structural differences compared with cortisol, the endogenous active glucocorticoid, are shown in *red*.

nase (11β-HSD) type 1. The same enzyme can also promote the reverse reaction by dehydrogenation, leading to inactivation of active glucocorticoids. In contrast, 11β-HSD type 2 only has dehydrogenase activity, so it only catalyzes the conversion of active glucocorticoids to their inactive forms. In different tissues, local balance between the intra-cellular enzymes 11β-HSD type 1 and type 2 might modulate intracellular glucocorticoid concentrations and thus tissue sensitivity for glucocorticoids.[7] Synovial tissue metabolizes glucocorticoids via the two 11β-HSD enzymes, with the net effect being glucocorticoid activation. This endogenous glucocorticoid production in the joint increases with joint

inflammation and, vice versa, has an impact on local inflammation and on bone of the joint.[8]

## GENOMIC AND NONGENOMIC MODES OF ACTION

Glucocorticoids at any therapeutically relevant dosage exhibit pharmacologic effects via classic genomic mechanisms. The lipophilic glucocorticoid passes across the cell membrane, attaches to the cytosolic glucocorticoid receptor and heat shock protein. These glucocorticoid complexes then bind to glucocorticoid-responsive elements of genomic DNA, or interact with nuclear transcription factors. This process takes time. When acting through genomic mechanisms, it takes at least 30 minutes before the clinical effect of a glucocorticoid begins to show.[9] Only when high doses are given, such as in pulse therapy, do nongenomic mechanisms also occur, by which glucocorticoids act within minutes. The response to high-dose pulse methylprednisolone therapy may be biphasic, consisting of an early, rapid, nongenomic effect and a more delayed and more sustained genomic effect.[10] Clinically, however, genomic and nongenomic effects cannot be separated.

### Genomic Mechanisms

Most of the effects of glucocorticoids are exerted via genomic mechanisms by binding to the glucocorticoid receptor located in the cytoplasm of the target cells. Glucocorticoids are lipophilic and have a low molecular mass, and thus they can pass through the cell membrane easily. Next to the tissue-specific intra-cellular density of glucocorticoid receptors, the balance of intra-cellular 11β–HSDs (described earlier) probably determines the sensitivity of specific tissues for glucocorticoids.[7] Of the isoforms α and β of the glucocorticoid receptor, only the α isoform, commonly present in all target tissues, binds to glucocorticoids. This is a 94 kDa protein to which several heat shock proteins (chaperones) are bound. Binding of the glucocorticoid to this complex causes shedding of the chaperones. The resulting activated glucocorticoid receptor–glucocorticoid complex is rapidly translocated into the nucleus, where it binds as a dimer to specific consensus sites in the DNA (glucocorticoid-responsive elements) regulating (i.e., stimulating or suppressing) the transcription of a large variety of target genes. This process is termed *transactivation*. Activated glucocorticoid receptor–glucocorticoid complexes also, as monomers, interact with transcriptional factors (such as activator protein-1, interferon regulatory factor-3, and nuclear factor-κB [NF-κB]), leading to inhibition of binding of these transcriptional factors to their consensus sites in the DNA.[11] This process, resulting in downregulation of predominantly pro-inflammatory protein synthesis, is called *transrepression* (Figure 60-4).

The nature and availability of transcription factors may be pivotal in determining the differential sensitivity of different tissues to glucocorticoids because these factors play a crucial role in regulating the expression of a wide variety of pro-inflammatory genes induced by cytokines. The inhibited binding of transcriptional factors to DNA by glucocorticoids results in depressed expression of these genes and inhibition of their amplifying role in inflammation.

The hypothesis has been proposed that adverse effects of glucocorticoids may be based predominantly on transactivation, whereas the anti-inflammatory effects may be mostly due to transrepression. Understanding of these molecular mechanisms could lead to the development of novel glucocorticoids, such as selective glucocorticoid receptor agonists, with a more favorable balance of transactivation and transrepression and, clinically, to a more favorable balance of metabolic and endocrine adverse effects and therapeutic effects.[11] However, although many immunosuppressive effects are based on transrepression, some effects are based on transactivation, such as glucocorticoid-induced gene transcription and protein synthesis of NF-κB inhibitor[12] and of lipocortin-1. Some immunosuppressive effects of glucocorticoids are not based on either transrepression or transactivation. Post-transcriptional mRNA destabilization resulting in decreased protein synthesis may also be an important anti-inflammatory mechanism of glucocorticoids. This mechanism has been proposed to mediate glucocorticoid-induced inhibition of the synthesis of interleukin (IL)-1, IL-6, granulocyte-macrophage colony-stimulating factor, and inducible cyclooxygenase (COX)-2.[13] On the other hand, not all adverse effects are related to transactivation; increased risk of infection is associated with immunosuppression, primarily based on transrepression, which is also the mechanism of suppression of the hypothalamic-pituitary-adrenal (HPA) axis. Moreover, a study in a mouse strain with a deficiency to form dimer glucocorticoid receptor–glucocorticoid complexes and thus with a transactivation deficiency showed, along with a failure of glucocorticoids to exert a full anti-inflammatory response, classic adverse effects in these mice, such as osteoporosis.[14] These data challenge the concept of selective glucocorticoid receptor agonists[15]; furthermore, in an asthma trial, the effect of a selective glucocorticoid receptor agonist was disappointing.[16]

### Nongenomic Mechanisms

Compared with genomic effects, nongenomic effects at high doses of glucocorticoids occur more rapidly—within minutes. One mechanism involves membrane-bound glucocorticoid receptors. Dexamethasone targets these receptors on T lymphocytes, which rapidly impairs T lymphocyte receptor signaling and immune response.[17] Nongenomic actions without involvement of glucocorticoid receptors occur via physicochemical interactions with biologic membranes, altering cell function. For instance, the resulting inhibition of calcium and sodium cycling across the plasma membrane of immune cells contributes to rapid immunosuppression and reduced inflammation.[5]

## GLUCOCORTICOID EFFECTS ON HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

### Hypothalamic-Pituitary-Adrenal Axis and Inflammation

Pro-inflammatory cytokines (such as IL-1 and IL-6), eicosanoids (such as prostaglandin $E_2$), and endotoxins all activate corticotropin-releasing hormone (CRH) at the

hypothalamic level and adrenocorticotropic hormone (ACTH) at the pituitary level. CRH also activates ACTH, and this activation stimulates the secretion of glucocorticoids by the adrenal glands, which is also stimulated by the inflammatory mediators previously mentioned (Figure 60-5). In otherwise healthy persons with severe infections or other major physical stress, cortisol production may increase to six times the normal amount.[18] In patients with chronic inflammatory diseases, such as active RA, this increase of cortisol driven by elevated cytokine levels might be inappropriately low,[19] meaning that cortisol levels, although normal or elevated in the absolute sense, are insufficient to control the inflammatory response. This is the concept of relative adrenal insufficiency.[19-22] Endogenous and exogenous glucocorticoids exert negative feedback control on the HPA axis *directly* by suppressing secretion of ACTH and CRH and also *indirectly* in inflammatory diseases by suppressing the release from inflammatory tissues of pro-inflammatory cytokines that stimulate secretion of ACTH and CRH (see Figure 60-5). Sensitivity of the HPA axis for pro-inflammatory cytokines is probably decreased in persons with RA.[23]

ACTH is secreted in brief, episodic bursts, resulting in relatively sharp increases in plasma concentrations of ACTH and cortisol, followed by slower declines in cortisol levels—the normal diurnal rhythm in cortisol secretion. Secretory ACTH episodic bursts increase in amplitude but not in frequency after 3 to 5 hours of sleep, reach a maximum in the hours before and the hour after awakening, decline throughout the morning, and are minimal in the evening. Cortisol levels are highest at about the time of awakening in the morning, are low in the late afternoon and evening, and reach their lowest level some hours after falling asleep (see Figure 60-5). Glucocorticoids are not stored in the adrenal glands in great quantities; continuing synthesis and release are required to maintain basal secretion or to increase blood levels during stress. The total daily basal or physiologic secretion of cortisol in humans has been estimated to range from 5.7 to 10 mg/m$^2$/day.[24,25] Although during periods of physiologic stress the replacement dose should be higher (discussed later), this need would be covered in persons with primary adrenal insufficiency by oral administration of 15 to 25 mg of cortisol,[24] equivalent to about 4 to 6 mg of prednisolone. This low daily cortisol production rate may explain the cushingoid symptoms and other adverse effects that are sometimes observed in patients with adrenal insufficiency who use glucocorticoids at doses previously regarded to be replacement doses (based on estimates of physiologic secretion of cortisol of 12 to 15 mg/m$^2$/day) but that are in fact supraphysiologic doses.

## Tertiary Adrenal Insufficiency

Chronic suppression of the HPA axis by administration of exogenous glucocorticoids, as a result of negative feedback loops on CRH and ACTH (see Figure 60-5), leads to failure of pituitary ACTH release and thus to partial functional adrenal atrophy with loss of cortisol secretory capability. Although this adrenal insufficiency is a result of the use of glucocorticoids (thus is secondary to glucocorticoids), and although ACTH release is also directly inhibited by glucocorticoids, this adrenal insufficiency is often referred to as tertiary adrenal insufficiency, referring to the inhibition of CRH release.[26] The inner adrenal cortical zone (i.e., the fasciculate-reticularis zone) is the site of cortisol and adrenal androgen synthesis and is dependent on ACTH for structure and function. The outer cortical zone (glomerulosa zone) is involved in biosynthesis of mineralocorticoids (aldosterone) and is functionally independent of ACTH. It stays functionally intact. Patients experience a failure of pituitary CRH and ACTH release and adrenal responsiveness to ACTH. Serum cortisol, ACTH levels, and adrenal responsiveness to ACTH are low, but other pituitary axes function normally, in contrast to the situation in most primary pituitary disorders. Tertiary adrenal insufficiency generally has a less dramatic presentation than primary adrenal insufficiency because aldosterone levels, which are controlled predominantly by the renin-angiotensin system, are preserved; thus mineralocorticoid therapy is not necessary.

The duration of glucocorticoid therapy leading to suppression of the HPA axis depends on the dosage and the serum half-life of the glucocorticoid used, but it also varies among patients, probably because of individual differences in glucocorticoid sensitivity and rates of glucocorticoid metabolism. Prediction with certainty of chronic suppression of the hypothalamic-pituitary-adrenal axis and adrenal insufficiency on the patient level is not possible. This risk may be increased when glucocorticoids are used concomitantly with other steroid drugs such as megestrol acetate and medroxyprogesterone, also inhibiting the HPA axis.[27]

The duration of anti-inflammatory effect of one dose of a glucocorticoid approximates the duration of HPA suppression. After a single oral dose of 250 mg of hydrocortisone or cortisone, 50 mg of prednisone or prednisolone, or 40 mg of methylprednisolone, suppression for 1.25 to 1.5 days has been described. Duration of suppression after 40 mg of triamcinolone or 5 mg of dexamethasone was 2.25 and 2.75 days, respectively.[28] After intramuscular administration of a single dose of 40 to 80 mg of triamcinolone acetonide, the duration of HPA suppression is 2 to 4 weeks, and after administration of 40 to 80 mg of methylprednisolone, suppression lasts 4 to 8 days.[28]

After 5 to 30 days of taking at least 25 mg of prednisolone or its equivalent daily, suppression of adrenal response (measured by a low-dose corticotropin test) was present in 34 of 75 patients studied (45%).[29] In these patients, a basal plasma cortisol concentration less than 100 nmol/L was highly suggestive of adrenal suppression, whereas levels of basal cortisol greater than 220 nmol/L predicted a normal adrenal response in most, but not all, patients.

The risk of clinical (symptomatic) adrenal insufficiency is not negligible in patients on long-term low-dose or medium-dose therapy—for example, those who have had less than 10 mg of prednisolone or its equivalent per day in one dose in the morning. Investigators who performed a review of adrenal insufficiency stated that if the daily dose is 7.5 mg or more of prednisolone or its equivalent for at least 3 weeks, adrenal hypofunctioning should be anticipated, and acute cessation of glucocorticoid therapy in this situation could lead to problems.[18] In 21 patients with RA who were undergoing long-term glucocorticoid therapy (a

mean daily dose of 6.7 mg prednisone equivalents), 52% had a normal (≥5 μg/dL) increase of serum cortisol after an intravenous 30-second bolus injection of 100 μg of human CRH, 33% had a subnormal response of cortisol, and 14% had no response at all.[30] Even patients who have received glucocorticoids for less than 3 weeks or have been treated with alternate-day prednisolone therapy do not have zero risk of suppression of the HPA axis, depending on the dose,[31,32] but the risk is low.

Thus adrenal suppression is difficult to predict, and it probably occurs frequently in daily practice.[33] It seems prudent to consider each patient who is undergoing chronic glucocorticoid therapy as being at risk for tertiary adrenal insufficiency. However, after slow tapering, glucocorticoid therapy often can be stopped (if there is no indication for this therapy any longer); generally, adrenal function gradually recovers during the slow tapering period.

## GLUCOCORTICOID EFFECTS ON THE IMMUNE SYSTEM

Glucocorticoids reduce activation, proliferation, differentiation, and survival of a variety of inflammatory cells, including macrophages and T lymphocytes, and promote apoptosis, especially in immature and activated T cells (Figure 60-6). This activity is mediated mainly by changes in cytokine production and secretion. In contrast, B lymphocytes and neutrophils are less sensitive to glucocorticoids, and their survival may be increased by glucocorticoid treatment. The main effect of glucocorticoids on neutrophils seems to be inhibition of adhesion to endothelial cells. Glucocorticoids inhibit not only the expression of adhesion molecules but also the secretion of complement pathway proteins and prostaglandins. At supraphysiologic concentrations, glucocorticoids suppress fibroblast proliferation and IL-1 and tumor necrosis factor (TNF)-induced metalloproteinase synthesis. By these effects, glucocorticoids may retard bone and cartilage destruction in inflamed joints of patients with early phase RA.[34,35]

### Leukocytes and Fibroblasts

Administration of glucocorticoids leads to an increase in the total leukocyte count because of an increase of circulating neutrophil granulocytes in the blood, although the numbers of other leukocyte subsets in blood, such as eosinophil and basophil granulocytes, monocytes/macrophages (decreased myelopoiesis and bone marrow release), and T cells (redistribution effect), are decreased. Table 60-2 summarizes the effects of glucocorticoids on leukocyte subsets. The redistribution of lymphocytes, which is maximal 4 to 6 hours after administration of a single high dose of prednisone and returns to normal within 24 hours, has no clinical consequences. B cell function and immunoglobulin production are hardly affected. The effects of glucocorticoids on monocytes and macrophages, including decreased expression of class II major histocompatibility complex (MHC) molecules and Fc receptors, may increase susceptibility to infection, however.[36] Effects of glucocorticoids on fibroblasts include decreased proliferation and decreased production of fibronectin and prostaglandins.

**TABLE 60-2** Anti-inflammatory Effects of Glucocorticoids on Immune Cells

| Cell Type | Effects |
|---|---|
| Neutrophils | Increased blood count, decreased trafficking, relatively unaltered functioning |
| Macrophages and monocytes | Decreased blood count, decreased trafficking, decreased phagocytosis and bactericidal effects, inhibited antigen presentation, decreased cytokine and eicosanoid release |
| Lymphocytes | Decreased blood count, decreased trafficking, decreased cytokine production, decreased proliferation and impaired activation, little effect on immunoglobulin synthesis |
| Eosinophils | Decreased blood count, increased apoptosis |
| Basophils | Decreased blood count, decreased release of mediators of inflammation |

### Cytokines

The influence of glucocorticoids on cytokine production and action represents one of the major mechanisms of glucocorticoid action in chronic inflammatory diseases. Glucocorticoids exert potent inhibitory effects on the transcription and action of a large variety of cytokines. Most T helper (Th) type 1 pro-inflammatory cytokines are inhibited by glucocorticoids, including IL-1β, IL-2, IL-3, IL-6, TNF, and interferon-γ, along with IL-17 (associated with Th17 cells), and granulocyte-macrophage colony-stimulating factor (see Figure 60-6). In persons with RA, these cytokines are considered to be responsible for synovitis, cartilage degradation, and bone erosion. Conversely, the production of Th2 cytokines, such as IL-4, IL-10, and IL-13, may be stimulated or not affected by glucocorticoids (see Figure 60-6).[37] These cytokines have been related to the extra-articular features of erosive RA associated with B cell overactivity, such as immune complex formation and vasculitis. Activation of Th2 cells can suppress rheumatoid synovitis and joint destruction through release of the anti-inflammatory cytokines IL-4 and IL-10, which inhibit Th1 activity and downregulate monocyte and macrophage functions.[38]

### Inflammatory Enzymes

An important part of the inflammatory cascade is arachidonic acid metabolism, which leads to the production of prostaglandins and leukotrienes, most of which are strongly pro-inflammatory. Through the induction of lipocortin (an inhibitor of phospholipase A2), glucocorticoids reduce the formation of arachidonic acid metabolites. Glucocorticoids also inhibit the production of COX-2 and phospholipase A2 induced by cytokines in monocytes/macrophages, fibroblasts, and endothelial cells. In addition, glucocorticoids are potent inhibitors of the production of metalloproteinases in vitro and in vivo, especially collagenase and stromelysin, which are the main effectors of cartilage degradation induced by IL-1 and TNF.[39]

### Adhesion Molecules and Permeability Factors

Pharmacologic doses of glucocorticoids markedly inhibit exudation of plasma and migration of leukocytes into

inflammatory sites. Adhesion molecules play a central role in chronic inflammatory diseases by controlling the trafficking of inflammatory cells into sites of inflammation. Glucocorticoids reduce the expression of adhesion molecules through the inhibition of pro-inflammatory cytokines and by direct inhibitory effects on the expression of adhesion molecules, such as intercellular adhesion molecule-1 and E-selectin.[40] Chemotactic cytokines attracting immune cells to the inflammatory site, such as IL-8 and macrophage chemoattractant proteins, also are inhibited by glucocorticoids. Nitric oxide production in inflammatory sites is increased by pro-inflammatory cytokines, resulting in increased blood flow, exudation, and probably amplification of the inflammatory response. The inducible form of nitric oxide synthase by cytokines is potently inhibited by glucocorticoids.[41]

## PHARMACOLOGY AND CLINICAL CONSIDERATIONS

### Pharmacokinetics

Apart from the steroid configuration, biologic characteristics of glucocorticoids also depend on whether they are in free form (as alcohol) or are chemically bound (as ester or salt). In their free form, glucocorticoids are virtually insoluble in water, so they can be used in tablets but not in parenteral preparations. For this reason, synthetic glucocorticoids are formulated as either organic esters or as salts. Esters, such as (di)acetate and (hex)acetonide, are lipid soluble but have limited water solubility and are suitable for oral use and intramuscular, intralesional, and intra-articular injection. Salts, such as sodium phosphate and sodium succinate, are generally more water soluble and thus are also suitable for intravenous use. Dexamethasone sodium phosphate can be used intravenously, whereas dexamethasone acetate cannot. When given intramuscularly, dexamethasone sodium phosphate is absorbed much faster from the injection site than dexamethasone acetate. If an immediate effect is required, dexamethasone sodium phosphate should be administered intravenously because it has a more rapid effect than the same preparation given intramuscularly. Intramuscular administration of dexamethasone acetate has the least rapid effect. For local use, less solubility means longer duration of the local effect, which generally is beneficial.

Water insolubility does not impair absorption from the digestive tract. Most orally administered glucocorticoids, whether in free form or as an ester or salt, are absorbed readily, probably within about 30 minutes. The bioavailability of prednisone and prednisolone is high. Commercially available oral and rectal prednisone and prednisolone preparations are considered approximately bioequivalent.

The affinity of the different glucocorticoids for various plasma proteins varies (see Table 60-1). Of cortisol in plasma, 90% to 95% is bound to plasma proteins, primarily transcortin (also called corticosteroid-binding globulin) and, to a lesser degree, albumin. Protein-bound cortisol is not biologically active, but the remaining 5% to 10% of free cortisol is biologically active. In contrast to methylprednisolone, dexamethasone, and triamcinolone, prednisolone has a high affinity for transcortin and competes with cortisol for this binding protein. Two-thirds of the other synthetic glucocorticoids with little or no affinity for transcortin are (weakly) bound to albumin, so about one-third circulates as free glucocorticoid.

Because only unbound glucocorticoids are pharmacologically active, patients with low levels of plasma proteins, such as albumin (e.g., because of liver diseases or chronic active inflammatory diseases), are more susceptible to effects and adverse effects of glucocorticoids. Dosage adjustment should be considered in these patients. In persons with liver disease, an additional argument for dosage adjustment is reduced clearance of glucocorticoids (discussed later).

Glucocorticoids have biologic half-lives 2 to 36 times longer than their plasma half-lives (see Table 60-1). Because prednisolone has a plasma half-life of about 3 hours, it can be prescribed in a once-daily dose for most diseases. Maximal effects of glucocorticoids lag behind peak serum concentrations. Transcortin binds these compounds more strongly than does albumin. The plasma elimination of glucocorticoids predominantly bound to transcortin is in general slower than that of glucocorticoids predominantly bound to albumin or that of glucocorticoids that do not bind to plasma proteins. Transcortin binding is not a major determinant of *biologic* half-lives of glucocorticoids, but it is a major determinant of distribution to different compartments of the body and of binding to the cytosolic glucocorticoid receptor. Compared with cortisol, synthetic glucocorticoids have a lower affinity for transcortin but a higher affinity for the cytosolic glucocorticoid receptor (discussed later). The affinity of prednisolone and triamcinolone for the glucocorticoid receptor is approximately two times higher, and for dexamethasone it is seven times higher. Before they have been chemically reduced, prednisone and cortisone have negligible glucocorticoid bioactivity because of their very low affinity for the glucocorticoid receptor.

Another important factor determining biologic half-lives of glucocorticoids is the rate of metabolism. Synthetic glucocorticoids are subject to the same reduction, oxidation, hydroxylation, and conjugation reactions as cortisol. Pharmacologically active glucocorticoids are metabolized primarily in the liver into inactive metabolites that are excreted by the kidneys; only small amounts of unmetabolized drug also are excreted in the urine. An inverse correlation has been found between prednisolone clearance and age, which means that a given dose may have a greater effect in older persons.[42] Prednisolone clearance also is slower in African Americans compared with the clearance in Caucasians.[43] The serum half-life of prednisolone is 2.5 to 5 hours, but it is increased in patients with renal disease and liver cirrhosis and in elderly persons. Prednisolone can be removed by hemodialysis, but overall, the amount removed does not require dosage adjustment in patients undergoing hemodialysis. In patients with cirrhosis of the liver, the clearance of unbound steroid is about two-thirds of normal, a difference that should be taken into account with dosing.

### Glucocorticoid Resistance

A small proportion of patients do not react favorably to glucocorticoids or even fail to respond to high doses. Furthermore, the susceptibility to adverse effects of

glucocorticoids varies widely. Several different factors are involved in the variability of glucocorticoid sensitivity in patients with rheumatic diseases,[44-46] and an understanding of the mechanisms involved might eventually permit their modulation.

Hereditary glucocorticoid resistance (which is rare) and increased susceptibility to glucocorticoids have been related to specific polymorphisms of the glucocorticoid receptor gene. The glucocorticoid receptor exists as α and β isoforms, but only the α isoform binds glucocorticoids. The β isoform functions as an endogenous inhibitor of glucocorticoids and is expressed in several tissues. Glucocorticoid resistance has been associated with enhanced expression of this β receptor, but this is unlikely to be an important mechanism for glucocorticoid resistance because in most cells, apart from neutrophilic granulocytes, expression of the β receptor is much less than that of the α receptor.[44] The protein lipocortin-1 (or annexin-1) inhibits eicosanoid synthesis. Glucocorticoids are thought to stimulate lipocortin-1. In patients with RA, autoantibodies to lipocortin-1 have been described. The titers in these patients correlate with the levels of maintenance doses of glucocorticoids, suggesting that these antibodies may lead to glucocorticoid resistance.[47]

Glucocorticoids exert most of their immunosuppressive actions through inhibition of cytokine production; high concentrations of cytokines, especially IL-2, antagonize the suppressive effect of glucocorticoids in a dose-dependent manner.[48] The balance is usually in favor of glucocorticoids, but high local concentrations of cytokines may result in a localized glucocorticoid resistance that cannot be overridden by exogenous glucocorticoids. In addition, macrophage migration inhibitory factor may play a role in glucocorticoid resistance in RA. This pro-inflammatory cytokine is involved in TNF synthesis and T cell activation, suggesting a role in the pathogenesis of RA. Macrophage migration inhibitory factor is suppressed by higher concentrations of glucocorticoids, but it is induced by low concentrations, leading to stimulation of inflammation.[49] Other possible mechanisms of glucocorticoid resistance include activation of mitogen-activated protein kinase pathways by certain cytokines, excessive activation of transcription factor activator protein 1, reduced histone deacetylase-2 expression, and increased P-glycoprotein–mediated drug efflux.[44] Drugs also may play a role in glucocorticoid sensitivity and resistance (see next section, Drug Interactions).

## Drug Interactions

Cytochrome P450 (CYP) is a family of isozymes responsible for the biotransformation of several drugs. Drug interactions can be based on induction or inhibition of these enzymes. Certain drugs (e.g., barbiturates, phenytoin, and rifampin), by inducing CYP isoenzymes (e.g., CYP3A4), increase the metabolism (breakdown) of synthetic and natural glucocorticoids, particularly by enhancing hepatic hydroxylase activity, thus reducing glucocorticoid concentrations (see Figure 60-3). Indeed, rifampin-induced nonresponsiveness to prednisone in inflammatory diseases has been described,[50,51] as has rifampin-induced adrenal crisis in patients receiving glucocorticoid replacement therapy.[52] Clinicians should consider increasing the dosage of glucocorticoids in patients who are concomitantly treated with these medications.

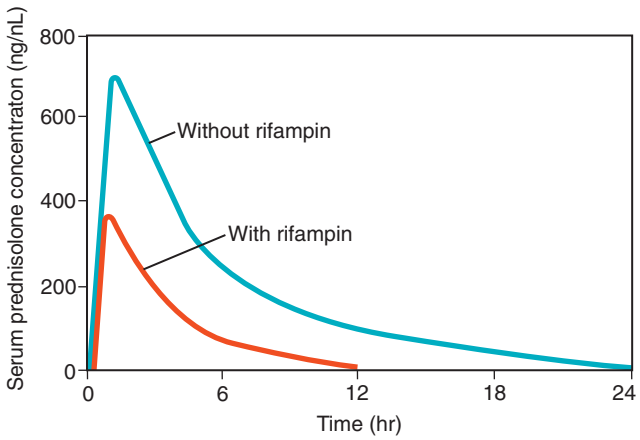

**Figure 60-3** Serum prednisolone concentration in time in one patient, after 0.9 mg/kg oral prednisone daily, in the presence and absence of therapy with rifampin. The *red* curve shows the concentration during a period of continuous administration of both prednisolone and rifampin. The *green* curve shows the concentration after a washout of rifampin of 4 weeks. Rifampin shows a reduced area under the curve, indicating reduced bioavailability of prednisolone during rifampin therapy.

Conversely, concomitant use of glucocorticoids with inhibitors of the drug metabolizing CYP3A4 (e.g., ketoconazole, itraconazole, diltiazem, mibefradil, and grapefruit juice) decreases glucocorticoid clearance and leads to higher concentrations and prolonged biologic half-life of glucocorticoid drugs, thus increasing the risk of adverse effects.[27] On the other hand, antifungal therapies, especially ketoconazole, are known to interfere with endogenous glucocorticoid synthesis and therefore are also used, in doses of 400 to 1200 mg per day, to treat hypercortisolism.[27] Etomidate, a short-acting intravenous anesthetic agent used for the induction of general anesthesia and for sedation, can also lower cortisol levels, which could be clinically relevant in critically ill patients.[27] However, in general, even potent CYP3A4 inhibitors are probably not that important for prednisone and prednisolone metabolism; in addition, the effect of grapefruit juice intake is likely to be of limited clinical significance.[53]

Concomitant administration of prednisolone and cyclosporine may result in increased plasma concentrations of the former drug, whereas concomitant administration of methylprednisolone and cyclosporine may result in increased plasma concentrations of the latter drug. The mechanism involved is probably competitive inhibition of microsomal liver enzymes. Antibiotics such as erythromycin may increase plasma concentrations of glucocorticoids. Synthetic estrogens in oral contraceptives increase the level of transcortin and thus total (the sum of bound and unbound) glucocorticoid levels. Therefore, in women taking oral contraceptives, care is required in the interpretation of cortisol measurements, especially because adrenal insufficiency may be present even if total cortisol levels are within the normal range.[18] Next to glucocorticoids, other steroid drugs such as megestrol acetate and medroxyprogesterone inhibit the HPA axis[27]; this risk may be increased when used concomitantly with glucocorticoids. Sulphasalazine has been reported to increase the sensitivity of immune cells for glucocorticoids,[54] which might be beneficial. Mifepristone is an

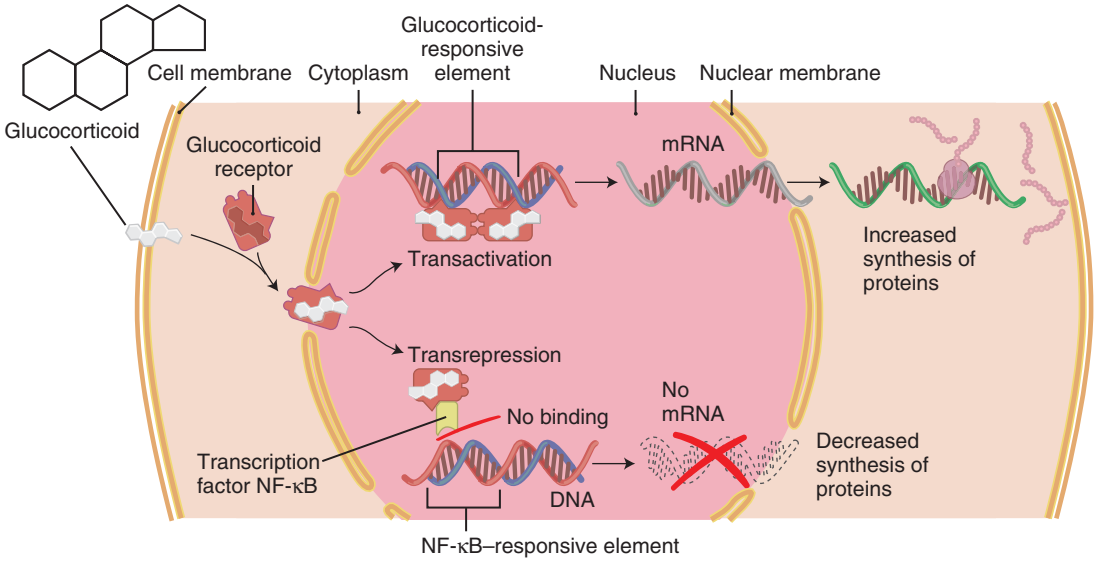

**Figure 60-4** Genomic action of glucocorticoids. Glucocorticoid binds to the glucocorticoid receptor (GCR) in the cytoplasm. This complex migrates into the nucleus. Activation of transcription (transactivation) by binding of GCR-glucocorticoid complex dimers to glucocorticoid-responsive elements of DNA upregulates synthesis of regulatory proteins, thought to be responsible for metabolic effects and also some anti-inflammatory/immunosuppressive effects. Interaction of GCR-glucocorticoid complex monomers with pro-inflammatory transcription factors, such as activator protein-1, interferon regulatory factor-3, and nuclear factor-κB (NF-κB) leads to inhibition of binding of these transcriptional factors to their DNA consensus sites (for NF-κB: NF-κB–responsive elements). Thus the transcription of these pro-inflammatory transcription factors is repressed. This process is called "transrepression" and downregulates synthesis of predominantly inflammatory/immunosuppressive proteins. mRNA, Messenger RNA. *(Modified from Huisman AM, Jacobs JW, Buttgereit F, et al: New developments in glucocorticoid therapy: selective glucocorticoid receptor agonists, nitrosteroids and liposomal glucocorticoids.* Ned Tijdschr Geneeskd *150:476-480, 2006.)*

**TABLE 60-3** Classification of Glucocorticoid Dosages

| | |
|---|---|
| Low dose | ≤7.5 mg prednisone equivalents per day |
| Medium dose | >7.5 mg and ≤30 mg prednisone equivalents per day |
| High dose | >30 mg and ≤100 mg prednisone equivalents per day |
| Very high dose | >100 mg prednisone equivalents per day |
| Pulse therapy | ≥250 mg prednisone equivalents per day for 1 day or a few days |

antiprogesterone drug and glucocorticoid receptor antagonist, and chlorpromazine inhibits glucocorticoid receptor–mediated gene transcription[55]; via these mechanisms, these drugs decrease the effect of glucocorticoids.

## GLUCOCORTICOID THERAPY

Glucocorticoids are widely used in various dosages for several rheumatic diseases. Often it is unclear what is meant by semiquantitative terms used for dosages, such as *low* or *high*. Based on pathophysiologic and pharmacokinetic data, standardization has been proposed to minimize problems in interpretation of these generally used terms (Table 60-3).[6]

### Indications

For each disease, indications for glucocorticoid therapy are discussed in the specific chapters related to the disease. An overview that summarizes only the general use and dosages of glucocorticoids is given here (Table 60-4). Without detailed description, some of the indications and dosages given in Table 60-4 could be considered questionable at first glance. In persons with systemic sclerosis, glucocorticoids, especially in high doses, are contraindicated because of the risk of scleroderma renal crisis, but they may be useful when myositis or interstitial lung disease complicates systemic sclerosis. Glucocorticoids are anchor drugs of the therapeutic strategy in myositis, polymyalgia rheumatica, giant cell arteritis, and systemic vasculitis. For other diseases, glucocorticoids serve as adjunctive therapy or are not used at all. For instance, in persons with RA, glucocorticoids are almost exclusively used as adjunctive therapy in combination with other disease-modifying anti-rheumatic drugs (DMARDs), described later. Glucocorticoids are not given to persons with osteoarthritis with the exception of an intra-articular injection if signs of synovitis of the osteoarthritic joint are present.[56] For generalized soft tissue disorders such as fibromyalgia, glucocorticoids are not indicated, and for localized soft tissue disorders, glucocorticoids should be used only for intralesional injection.[57]

### Glucocorticoid Therapy in Rheumatoid Arthritis

Glucocorticoids are frequently prescribed for persons with RA. Worldwide estimates of the percentages of patients with RA who are treated with glucocorticoids range from 15% to 90%.[58] Aims of this therapy are reduction of signs and symptoms and inhibition of the development of joint damage.

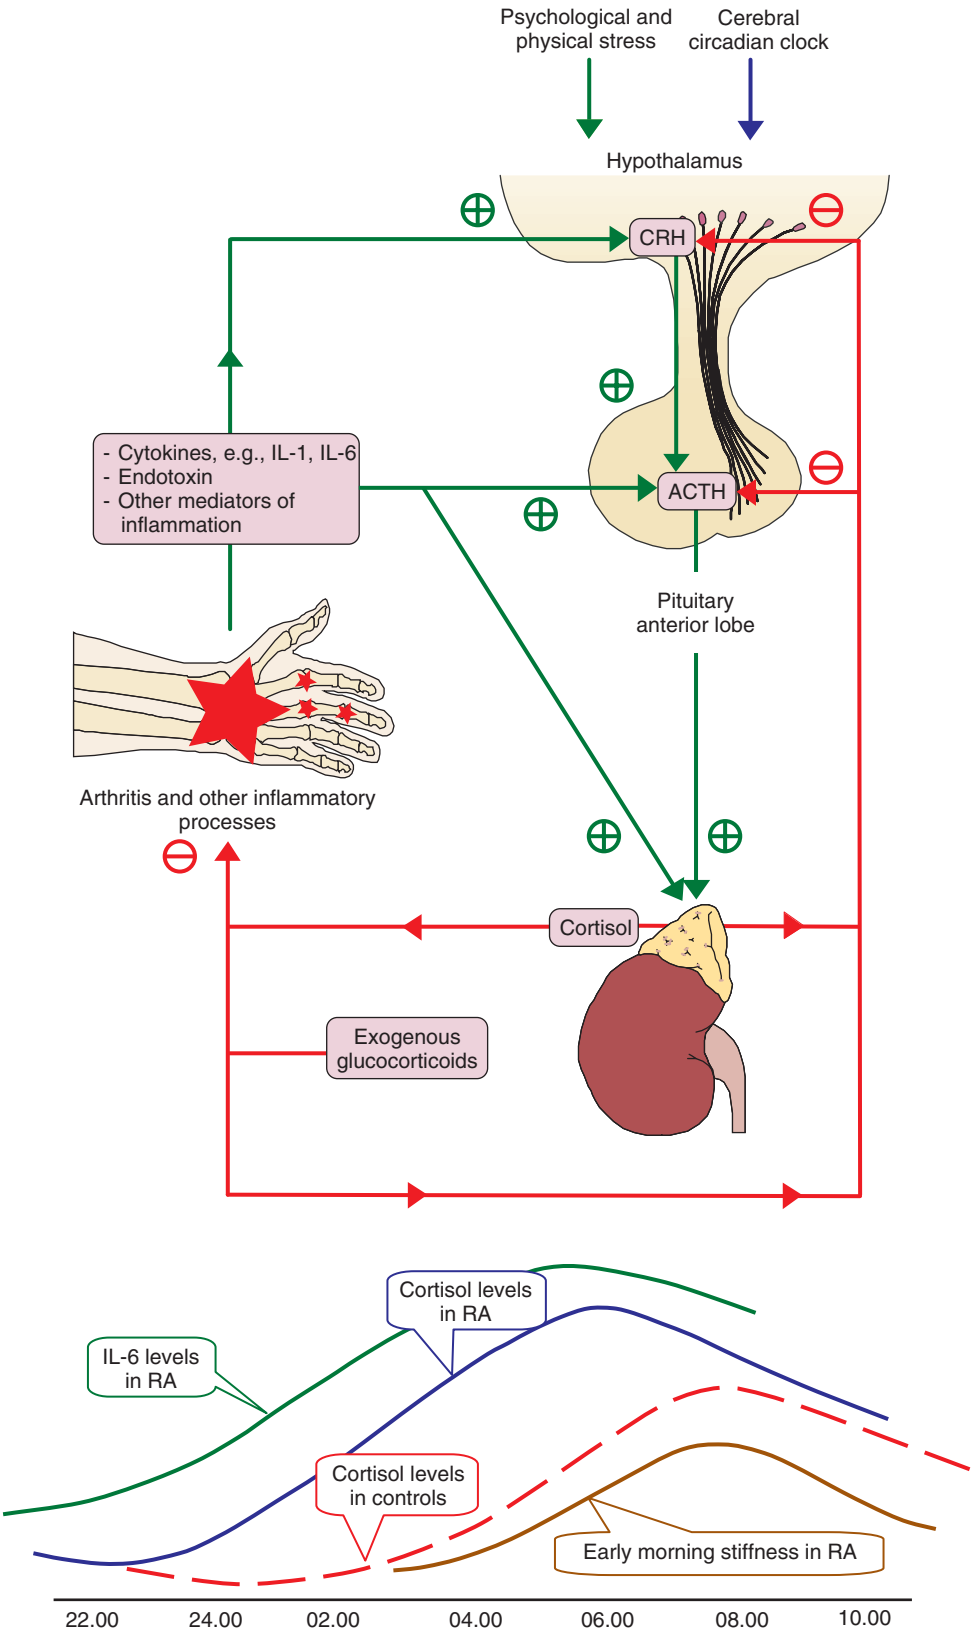

**Figure 60-5** *Upper part,* Stimulation (in *green*, plus signs) and inhibition (in *red*, minus signs) of the hypothalamic-hypopituitary-adrenal axis. *Lower part,* hours on the x-axis; plasma cortisol levels in patients with rheumatoid arthritis (RA) show an earlier and higher circadian rise compared with that in healthy control subjects, possibly caused by the rise in the pro-inflammatory cytokine interleukin (IL)-6; this IL-6 rise is absent in healthy control subjects. IL-6 stimulates the hypothalamus and thus the release of cortisol, but probably also contributes to early morning stiffness and other inflammatory symptoms in (rheumatoid) arthritis. ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

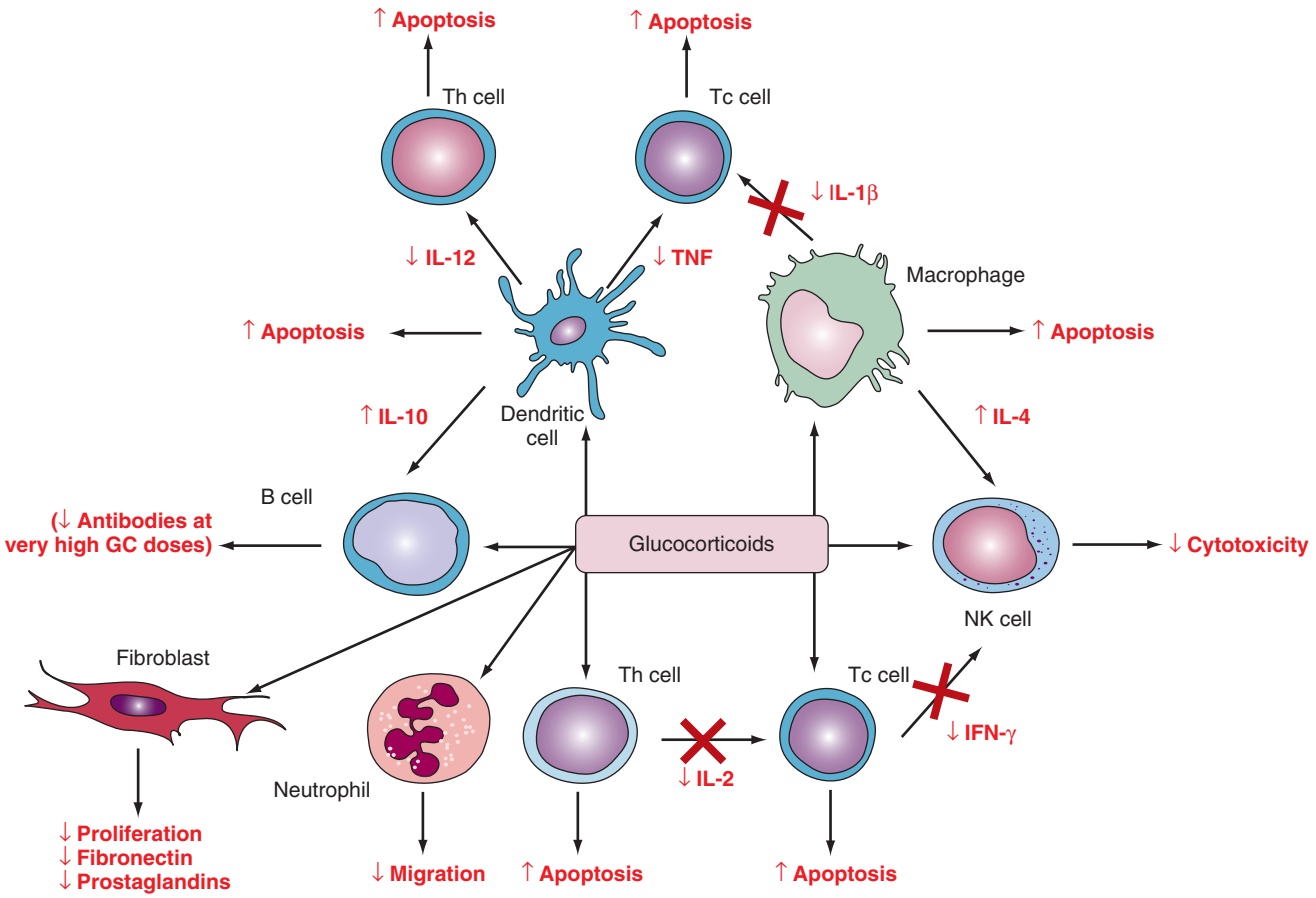

**Figure 60-6** Glucocorticoid (GC) effects (in *red*) on the interplay of inflammatory cells and cytokines. Glucocorticoids act on immune cells both directly and indirectly. The production of pro-inflammatory cytokines, such as interleukin (IL)-1β and tumor necrosis factor (TNF), is inhibited and the production of anti-inflammatory cytokines, such as IL-10, by macrophages and dendritic cells is stimulated. Glucocorticoids promote apoptosis of macrophages, dendritic cells, and T cells. All these effects result in inhibition of immune responses. IFN-γ, Interferon-γ; NK cell, natural killer cell; Tc, cytotoxic T cell; Th, T helper cell. *(Modified from Sternberg EM: Neural regulation of innate immunity: a coordinated nonspecific host response to pathogens.* Nat Rev Immunol *6:318-328, 2006.)*

*Initial dose is the dose at the start of therapy; it often will be decreased in time depending on disease activity. Doses in prednisone equivalents per day: low, ≤7.5 mg; medium, >7.5 but ≤30 mg; high, >30 but ≤100 mg; very high, >100 mg.

–, Rare use; 1, infrequent use, for therapy-resistant disease, complications, severe flare, major exacerbation, and for bridging the lag time of recently started therapy; 2, frequently added to/used as the basic therapeutic strategy; 3, basic part of the therapeutic strategy.

CCP, Calcium pyrophosphate; GCA, giant cell arteritis.

### Signs and Symptoms

As can be seen in Table 60-4, RA is the only disease in which glucocorticoid therapy is often started and maintained at a low or medium dose as additional therapy. The rationale for this therapy is a probable relative insufficiency of the adrenal gland in patients with active RA.[19] Glucocorticoids are highly effective for relieving symptoms in patients with active RA in doses of less than 10 mg of prednisolone or its equivalent per day. Because of its efficacy, many patients are functionally dependent on this therapy and continue it on a long-term basis.[59] A review of seven studies (including 253 patients) concluded that glucocorticoids, when administered for approximately 6 months, are effective for the treatment of RA.[60] After 6 months of therapy, the beneficial effects of glucocorticoids seem to diminish, but if this therapy is then tapered off and stopped, patients often—especially during the first months—experience aggravation of symptoms, which indicates that the glucocorticoid therapy was effective after all, and which partly can be ascribed to some grade of adrenal insufficiency by persistent suppression of the adrenal gland by the recent glucocorticoid therapy.

### Radiologic Joint Damage: Glucocorticoids as Disease-Modifying Anti-rheumatic Drugs

In 1995, the joint-preserving effects of 7.5 mg of prednisolone daily for 2 years were described in patients with RA of short and intermediate duration who also were treated with DMARDs. The group of patients with RA who participated in this randomized, placebo-controlled trial was heterogeneous, not only with respect to disease duration, but also with respect to stages of the disease and types and dosages of DMARDs.[61] In another trial published in 1997, patients with early phase RA were randomly assigned to step-down therapy with two DMARDs (sulphasalazine and methotrexate) and prednisolone (starting with 60 mg/day, tapered in six weekly steps to 7.5 mg/day, and stopped at 34 weeks) or sulphasalazine alone. For the combined drug strategy, a statistically significant and clinically relevant effect in retarding joint damage was shown compared with the effect of sulfasalazine alone.[62] In an extension of this study, long-term beneficial benefits (up to 11 years) were shown regarding radiologic damage after the combination strategy.[63,64] It has been hypothesized that the superior effect of the combination therapy in this trial can be ascribed to the prednisolone because in three double-blind, randomized trials, the effect of the combination of methotrexate and sulphasalazine was not superior to that of either drug alone.[65-67]

In a German study, 200 patients with early phase RA were treated with methotrexate or intramuscular gold and were randomly assigned for additional treatment with 5 mg of prednisolone or placebo. After 2 years, less progression of radiologic damage occurred in the prednisolone-treated patients than in those treated with placebo.[68] In 2002, the results of the Utrecht study on the effects of 10 mg of prednisolone daily in DMARD-naïve patients with early RA were published. This trial is the only placebo-controlled trial in which prednisolone was applied as DMARD monotherapy as a first step; other DMARDs were added only as rescue medications, which would be considered unethical today. The progression of radiologic joint damage was inhibited by prednisolone in these patients.[69] The Utrecht study reported a 40% decreased need for intra-articular glucocorticoid injections, a 49% decreased need for acetaminophen use, and a 55% decreased need for nonsteroidal anti-inflammatory drugs (NSAIDs) in the prednisolone group compared with the placebo group. These findings indicate that in clinical trials evaluating the clinical effect of DMARDs or glucocorticoids, these additional therapies should be taken into account.[70] In an extension of this study, at 3 years after the end of the 2-year study, after which prednisolone therapy was tapered off and stopped, yearly radiologic progression, albeit substantial, was statistically significantly less in the group that formerly received prednisolone.[71]

In another 2-year study in 250 patients with early phase RA, 7.5 mg/day of prednisolone added to DMARD therapy also retarded joint damage and increased the remission rate compared with placebo added to DMARDs.[72]

Another form of glucocorticoid therapy in RA is the monthly intramuscular application of 120 mg of depot methylprednisolone acetate. However, in contrast to oral glucocorticoids, this treatment showed only a small effect on joint erosion progression at the cost of a significant increase in adverse events.[73]

Studies showing no effect of glucocorticoids on radiologic damage have also been published,[74-76] but in early phase RA, evidence of the joint-sparing effects of glucocorticoids, which persist after therapy is stopped, is convincing, classifying glucocorticoids as DMARDs. A meta-analysis of radiographic outcome analyzed 15 studies of glucocorticoids (two with negative results) that included in total 1414 patients; most studies used a dose of 5 to 10 mg/day of prednisolone or its equivalent for 1 to 2 years. Because different methods had been used in the individual trials, radiographic scores were expressed as a percentage of the maximum possible score for the specific radiographic score method used. The standardized mean difference in progression was 0.40 in favor of strategies using glucocorticoids (95% confidence interval [CI], 0.27 to 0.54). This estimate was considered conservative because the most conservative estimate of the difference in each study had been chosen.[35]

These glucocorticoid studies described above did not have a tight control or treat-to-target design. The primary research question of the second Computer Assisted Management in Early RA clinical trial (CAMERA-II) was whether prednisone would still have disease-modifying properties in early phase RA when added to a highly effective,[77] tightly controlled, methotrexate-based computer-assisted strategy aimed at remission (treat-to-target).[78] Erosive joint damage after 2 years of therapy was limited in both strategy groups, but it was significantly less in the methotrexate-based strategy group that also received prednisone ($n$ = 117), compared with the strategy group that also received placebo ($n$ = 119; Figure 60-7). The strategy with prednisone also yielded more clinical improvement, in the form of earlier suppression of disease activity parameters, earlier sustained remission (after 6 months of therapy compared with after 11 months), and significantly less need to add TNF inhibitor therapy to the strategy to acquire remission. The occurrence of nausea and elevated serum

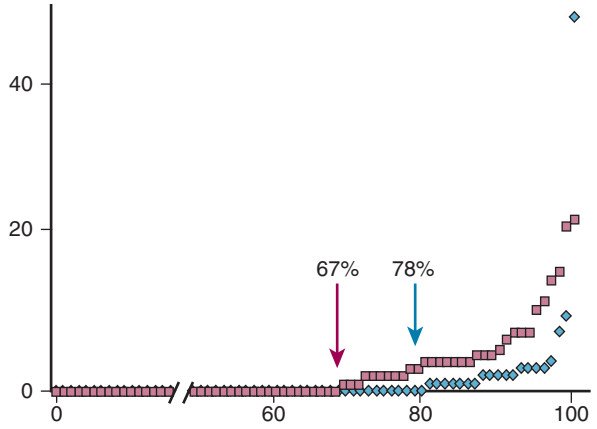

**Figure 60-7** Cumulative probability plots of erosion scores (y-axis: erosion score according to the van der Heijde modification of the Sharp method) at the end of the 2-year second Computer Assisted Management in Early RA clinical trial (CAMERA-II).[76] Each *blue diamond* represents a patient of the methotrexate-based treat-to-target strategy with prednisone, and each *red rectangle* represents a patient of the methotrexate-based treat-to-target strategy with placebo. The plot shows that 78% of patients in the prednisone strategy group versus 67% in the placebo strategy group was still erosion free after 2 years; of those who did have erosions, erosion scores were higher in the placebo strategy group compared with the prednisone strategy group, with exception of the score in one patient, who already had a high score at baseline. The median erosion score was statistically significantly lower in the prednisone strategy group compared with the placebo strategy group.

transaminases was less frequent in the prednisone group compared with the placebo group, probably because doses of methotrexate were significantly lower in the prednisone strategy group, which nevertheless was clinically more effective. The mean (standard deviation [SD]) of maximum dosages of methotrexate (oral or subcutaneous) during the trial was 19.7 (6.1) mg/wk for the methotrexate and prednisone group and 23.4 (4.5) mg/wk for the methotrexate and placebo group ($P$ <0.001). In the prednisone strategy group, mean weight gain after 2 years was 2.9 kg, which was significantly higher than the gain of 1.3 kg in the placebo group. However, in an additional analysis, the extra weight gain in the prednisone group seemed at least partly attributable to a better reduction of weight-loss–inducing disease activity by prednisone, rather than this weight gain representing solely an adverse effect of prednisone.[48] No difference in bone mineral density was found after 2 years between both groups, who received osteoporosis prophylaxis, nor was there a decrease of bone mineral density within each group.[49]

Other studies performed with glucocorticoids in early phase RA also show beneficial results.[79-81] However, because it has not been investigated properly, it is still not known whether glucocorticoids also can inhibit progression of erosions in RA of longer duration than 2 years. A so-called window of opportunity may exist for the treatment of RA.[82] If this window is real, effective treatment of early phase RA with glucocorticoids and other DMARDs results in a positive effect that lasts for a long time and results in disease activity that is easier to control, with less early joint damage. If treatment starts later or is less effective, this opportunity may be lost, resulting in more difficult control of disease activity, because then inflammation is probably also fuelled by joint damage. In addition, because glucocorticoid-induced osteoporosis and peptic ulcer complications (especially if glucocorticoids are combined with NSAIDs) can be prevented effectively, the joint-protective effect of prednisolone in RA during the first 2 years of the disease in a dose of 5 to 10 mg daily is a relevant finding. Long-term adverse effects of glucocorticoids are avoided if prednisolone is tapered and stopped (if possible) after these first 2 years.

The joint-sparing effect of glucocorticoids probably is based on the inhibition of pro-inflammatory cytokines such as IL-1 and TNF,[83] which stimulate osteoblasts and T cells to produce receptor activator of NF-κB (RANK) ligand. This ligand binds to RANK on osteoclast precursor cells and on mature osteoblasts, leading to activation of osteoclasts, which are responsible for bone resorption, periarticular osteopenia, and formation of bone erosions in RA. Furthermore, fibroblast proliferation and IL-1 and TNF-induced metalloproteinase synthesis are inhibited by glucocorticoids, retarding bone and cartilage destruction in inflamed joints of patients with early RA.[34,35,39]

### Prevention of Early Rheumatoid Arthritis Development with Glucocorticoids

Trials with glucocorticoids have been performed to try to prevent arthralgia or early arthritis from progressing to chronic arthritis. In patients who had (very) early phase arthritis or in persons with arthralgia and antibodies to citrullinated proteins or who had a positive rheumatoid factor test, intramuscular glucocorticoid injections did not prevent arthritis development in two placebo-controlled trials,[84,85] but in another placebo-controlled double-blind trial, these injections postponed the need for DMARD therapy and prevented progression into RA in 10% of patients at assessment at 12 months.[86] These results are preliminary and inconclusive, and it is clear that further research is needed.

## Glucocorticoid Pulse Therapy

Glucocorticoid pulse therapy is used in rheumatology, especially for remission induction, treatment of flares of inflammatory rheumatic disorders and vasculitides, and for severe complications of rheumatic diseases, such as visual loss in persons with giant cell arteritis. However, in 144 patients with biopsy-confirmed giant cell arteritis—91 with vision loss upon being seen initially and 53 without vision loss—no evidence was found that intravenous glucocorticoid pulse therapy (usually 150 mg dexamethasone sodium phosphate every 8 hours for 1 to 3 days) was more effective than high and very high doses of oral (80 to 120 mg) prednisone daily in preventing deterioration of vision.[87] In persons with active RA, pulse therapy to induce remission is often applied in the initiation phase of a (new) DMARD strategy to stabilize in the long term the remission induced by the pulse therapy. The beneficial effect of pulse therapy generally lasts about 6 weeks, with a large individual variation in the duration of the effect.[88] For this purpose, pulse therapy with schemes of 1000 mg of methylprednisolone per day intravenously for one or several days has been proven to be effective in many studies. Short-term effects of pulse therapy in patients with *established*, active RA at various dimensions of health status are very similar to long-term effects of effective

**TABLE 60-5** Glucocorticoid Tapering Scheme to Provide to Patients*

| | Monday | Tuesday | Wednesday | Thursday | Friday | Saturday | Sunday |
|---|---|---|---|---|---|---|---|
| Period 1 | High | High | High | High | Low | High | High |
| Period 2 | High | Low | High | High | High | Low | High |

| Period 7 | Low | Low | Low | Low | Low | Low | Low |
| Duration of each period ____ week(s)† | | | | Low = ____ mg/day† | | High = ____ mg/day† | |

*At each consecutive period, which can last 1 week, 2 weeks, or more weeks, depending on clinical considerations, the number of days per period at which a low dose is taken increases by 1. After completion of period 7, the next step in tapering can be taken; the dose called "low" during the previous seven periods now is "high." In case of aggravation of symptoms, the patient should not diminish the dose and should contact the physician.

†To be filled out by the physician.

conventional DMARD therapy, such as methotrexate, in patients with *early* phase RA.[89]

The risk of adverse effects of pulse therapy is not the same for all rheumatic disorders. Compared with patients with RA, patients with SLE more frequently experience osteonecrosis and psychosis as adverse effects of pulse therapy.[89] Osteonecrosis and psychosis also can be complications of SLE itself, however. Contraindications for pulse therapy are pregnancy and lactation, infections, current peptic ulcer disease, glaucoma, and insufficiently controlled hypertension and diabetes mellitus. In patients with well-controlled hypertension or diabetes mellitus or a family history of glaucoma, pulse therapy can be applied with checks of blood pressure and of blood glucose levels and eye pressure, respectively, before and during high-dose glucocorticoid therapy and pulse therapy.[90]

## Glucocorticoid Tapering Regimens

Because of potential adverse effects, glucocorticoids usually are tapered off as soon as the disease being treated is under control. Tapering must be performed carefully to avoid recurrent activity of the disease and cortisol deficiency resulting from chronic HPA axis suppression. Gradual tapering permits recovery of the adrenal function. There is no best scheme for tapering glucocorticoids based on controlled, comparative studies. Tapering depends on the specific disease being treated; furthermore, it depends on the clinical response and current disease activity and the doses and duration of glucocorticoid therapy, which all are influenced by the individual patient's glucocorticoid sensitivity. Only generic guidelines can be offered. To taper the dose of prednisone, decrements of 5 to 10 mg every 1 to 2 weeks can be applied when the prednisone dose is higher than 40 mg/day, followed by 5 mg decrements every 1 to 2 weeks at doses between 40 and 20 mg/day, and finally 1 to 2.5 mg/day decrements every 2 to 3 weeks at a prednisone dose of less than 20 mg/day. Another scheme is to taper 5 to 10 mg every 1 to 2 weeks down to 30 mg/day of prednisone, and when the dose is less than 20 mg/day, to taper 2.5 to 5 mg every 2 to 4 weeks down to 10 mg/day; thereafter, the dose may be tapered 1 mg each month or 2.5 mg (half a 5 mg tablet of prednisolone) each 7 weeks. For tapering steps over 7 weeks or a multiple number of 7 weeks, a printed schedule can be given to the patient, such as the one shown in Table 60-5, on which the doses and period of tapering should be filled out.

## Stress Regimens and Perioperative Care

Patients taking low-dose glucocorticoid medication on a long-term basis have suppressed adrenal activity and should be advised to double their daily glucocorticoid dose, or increase the dose to 15 mg prednisolone or its equivalent, if they experience fever attributed to infection; they should also seek medical help. In case of major surgery, given the unreliable prediction of adrenal suppression on the basis of the duration and dose of glucocorticoid therapy (see the section in this chapter on the effects of glucocorticoids on the HPA axis), many physicians recommend "stress doses" of glucocorticoids, also for patients with a low risk of adrenal suppression. The scheme of 100 mg of hydrocortisone administered intravenously just before the operation is performed, followed by an additional 100 mg every 6 hours for 3 days, is based on anecdotal information and is not always necessary.[91,92] A scheme with a lower dose, possibly reducing the risk of post-operative bacterial infectious complications, is to continuously infuse 100 mg of hydrocortisone intravenously the first day of surgery, followed by 25 to 50 mg of hydrocortisone every 8 hours for 2 or 3 days. Another option is to administer the usual dose of oral glucocorticoid orally or (the equivalent) parenterally on the day of surgery, followed by 25 to 50 mg of hydrocortisone every 8 hours for 2 or 3 days.

In cases of minor surgery, it is probably sufficient to double the oral dose or to increase the dose to 15 mg of prednisolone or its equivalent for 1 to 3 days. No comparative randomized studies on different perioperative glucocorticoid stress schemes have been published, however. Because aldosterone secretion is preserved in persons with glucocorticoid-induced tertiary adrenal insufficiency, mineralocorticoid therapy is unnecessary, whereas it is necessary in persons with primary adrenal insufficiency.

## Pregnancy and Lactation

In pregnancy, two mechanisms protect the fetus from exogenous glucocorticoids. First, glucocorticoids bound to

transport proteins cannot pass the placenta, in contrast to unbound glucocorticoids. Second, the enzyme 11β-HSD in the placenta, which catalyzes the conversion of active cortisol, corticosterone, and prednisolone into the inactive 11-dehydro-prohormones (cortisone, 11-dehydrocorticosterone, and prednisone), protects the fetus from glucocorticoids in the blood of the mother. The maternal-to-fetal prednisolone blood concentration ratio is about 10:1 as a result of these mechanisms. In contrast, dexamethasone has little or no affinity for transport proteins and is poorly metabolized by 11β-HSD in the placenta; the maternal-to-fetal dexamethasone blood concentration ratio is about 1:1.

If a pregnant woman must be treated with glucocorticoids, then prednisone, prednisolone, and methylprednisolone would be good choices; if the unborn child must be treated—for example, to treat congenital heart block associated with maternal Sjögren's syndrome—then fluorinated glucocorticoids, such as betamethasone or dexamethasone, would be indicated. The risk of adverse effects of antenatal exposure to glucocorticoids such as reduced intrauterine growth and birth weight, neurocognitive adverse effects, and oral cleft seems to be dependent on dose, duration of therapy, and stage of pregnancy. Several studies report conflicting results regarding the occurrence of these adverse effects,[93-95] but doses of glucocorticoid and indications for this therapy differ between studies. Furthermore, it is difficult to discriminate between negative effects and complications of the fetal condition treated and adverse effects of the glucocorticoid therapy. Avoidance of high doses (1 to 2 mg/kg prednisolone-equivalent) in the first trimester of pregnancy is advised,[96,97] whereas low to medium doses of prednisone seem to be safe.[97]

Early postnatal dexamethasone therapy for the prevention or treatment of chronic lung disease has been shown to have negative effects on neuromotor and cognitive function at school age.[98] Prednisolone and prednisone are excreted only in small quantities in breast milk. Breastfeeding is generally considered safe for an infant whose mother is taking these drugs. The exposure of the infant seems further minimized if the infant is breastfed before the mother takes her daily dose, or if breastfeeding is avoided during the first 4 hours after the intake of prednisolone, because curves of milk and serum concentrations of prednisolone are similar in time.[97]

## Intralesional and Intra-articular Glucocorticoid Injections

Injections with glucocorticoids are widely used for arthritis (see Table 60-4), tenosynovitis, bursitis, enthesitis, and compression neuropathies such as carpal tunnel syndrome.[57] Generally, the effect occurs within days; it can be long lasting, but if the underlying disease is active, the effect is of short duration. Administration of a local anesthetic concurrently with intra-articular or soft tissue injection of a glucocorticoid may provide immediate pain relief.

Soluble glucocorticoids (e.g., phosphate salts) have a more rapid onset of action and likely have less risk of subcutaneous tissue atrophy and depigmentation of the skin when given intralesionally. Insoluble glucocorticoids are longer acting and might decrease the soft tissue fibrous matrix to a greater extent than soluble glucocorticoids, so they should be used with caution in places with thin skin, especially in elderly patients and patients with peripheral vascular disease. Administration of insoluble glucocorticoids into deep sites is a safer approach. Short-acting soluble glucocorticoids can be mixed with long-acting insoluble glucocorticoids to combine rapid onset with long-acting effects.

The effect of an intra-articular glucocorticoid injection probably depends on several factors: the underlying disease (e.g., RA or osteoarthritis), characteristics of the treated joint (e.g., size and weight bearing or non–weight bearing), the activity of arthritis, the volume of synovial fluid of the treated joint,[46] the application of arthrocentesis (synovial fluid aspiration) before injection, the choice and dose of the glucocorticoid preparation, the application of rest to the injected joint, and the injection technique. The effect of injections seems to be less favorable in osteoarthritis compared with RA.[99] Arthrocentesis before injecting the glucocorticoid preparation reduces the risk for relapse of arthritis. Triamcinolone hexacetonide, which among the injectable glucocorticoids is the least soluble preparation, demonstrates the longest effect.

Theoretically, rest of the injected joint minimizes leakage of the injected glucocorticoid preparation to the systemic circulation (via the hyperemic, inflamed synovium by enhanced pressure in the joint during activity), minimizes the risk of cartilage damage, and optimizes the condition for repair of inflammatory tissue damage. Advice and procedures for the postinjection period in terms of activity vary from no restrictions, to minimal activity of the injected joint for a couple of days, to bed rest for 24 hours after injection of a knee joint or splinting of injected joints. Based on the literature, no definite evidence-based recommendation can be made, but it seems prudent to rest and not to overuse the injected joint for several days, even if pain is relieved.

It is recommended that intra-articular glucocorticoid injections be repeated no more than once every 3 weeks and be given no more frequently than three times a year in a weight-bearing joint (e.g., the knee) to minimize glucocorticoid-induced joint damage. This recommendation also seems sensible, but there is no definite clinical evidence to support it. As one would expect, accuracy of steroid placement influences the clinical outcome of glucocorticoid injections into the shoulder and probably into other joints as well.[100] This factor is important because it is estimated that a little more than half of shoulder injections are inaccurately placed.[100,101] The reported infection rate of joints after local injections with glucocorticoids is low, ranging from 1 case in 13,900 to 77,300 injections.[102,103] Introduction in the past of disposable needles and syringes has helped to reduce the risk of infection. In a 3-year prospective study in an urban area of 1 million people in the Netherlands, bacterial infections were detected in 214 joints (including 58 joints with a prosthesis or osteosynthetic material) of 186 patients; only 3 of these joint infections were attributed to an intra-articular injection.[104]

Other adverse effects of local glucocorticoid injections are systemic adverse effects of the glucocorticoid, such as disturbance of the menstrual pattern, hot flush–like

symptoms the day of or the day after injection, and hyperglycemia in persons with diabetes mellitus.[57] Local complications include subcutaneous fat tissue atrophy (especially after improper local injection), local depigmentation of the skin, tendon slip and rupture, and lesions to local nerves.[57]

## Improving the Therapeutic Ratio of Glucocorticoids

### Alternate-Day Regimens

For oral, long-term use of glucocorticoid therapy, alternate-day regimens have been devised in an attempt to alleviate adverse effects, such as HPA axis suppression. Alternate-day therapy consists of a single dose administered every other morning, which is usually equivalent to, or somewhat higher than, twice the usual or pre-established daily dose. The rationale for this regimen is that the body, including the HPA, exposed to exogenous glucocorticoid only on alternate days, may recover the other days. This rationale makes sense only for usage of a class and dosage of a glucocorticoid that suppresses the HPA axis activity for less than 36 hours after a single dose. Another prerequisite is that the patient should have a responsive HPA axis that has not been chronically suppressed by previous glucocorticoid regimens. The alternate-day schedule does not work in patients taking medium- or high-dose glucocorticoids on a long-term basis, which suppresses the HPA axis activity for longer than 36 hours.

Alternate-day therapy is unsuccessful in several inflammatory rheumatic diseases. Patients with RA often experience exacerbation of symptoms the day that no glucocorticoid is taken. This experience is in line with the clinical impression that a single dose of glucocorticoids daily is less effective in persons with RA than half that dose, given twice daily. In persons with giant cell arteritis, alternate-day glucocorticoid therapy also is less effective than daily administration.[106,107] Generally, alternate-day regimens are used rarely in rheumatology today, except in patients with juvenile idiopathic arthritis, in whom alternate-day glucocorticoid usage results in less inhibition of body growth than is associated with daily usage.[108] If treatment has been initiated with daily administration, the change to alternate-day therapy preferably should be made after the disease has stabilized.

### Glucocorticoid-Sparing Agents

For several inflammatory rheumatic diseases such as SLE, vasculitis, and myositis, early in the disease, other immunosuppressive drugs such as hydroxychloroquine, methotrexate, and, for systemic vasculitis, cyclophosphamide often are added to therapy with glucocorticoids. For these indications, increasingly, biologic agents also are used.[109] Exceptions are polymyalgia rheumatica and giant cell arteritis, which are managed primarily with glucocorticoids alone. Combination therapy is applied if it is known that the effect of the combination for the specific disease (e.g., systemic vasculitis) is better than that of glucocorticoids alone or if the disease (e.g., inflammatory myositis) seems resistant to the high initial doses of glucocorticoids.

If in a later stage of the disease immunosuppressive drugs are added to therapy with glucocorticoids to enable further reduction of the dose to decrease the risk of adverse effects, these immunosuppressive drugs are termed *glucocorticoid-sparing agents*. Azathioprine and methotrexate are often used for this purpose, although any drug that has an additive or synergistic effect in suppressing the disease activity, thus enabling reduction of the glucocorticoid dose, could be used as a glucocorticoid-sparing agent.

In persons with polymyalgia rheumatica and giant cell arteritis, azathioprine, antimalarial agents, cyclosporine, dapsone, infliximab, adalimumab, leflunomide, and most frequently methotrexate have been tried as glucocorticoid-sparing agents; half of the six randomized trials on methotrexate support its use in this situation.[110-115] A meta-analysis showed a marginal benefit of methotrexate as a glucocorticoid-sparing agent in giant cell arteritis with respect to relapse (relative risk [RR] 0.85; 95% CI, 0.66 to 1.11) and no improved outcome associated with the use of other glucocorticoid-sparing agents.[116]

### Modified-Release Prednisone

The inflammatory process and signs and symptoms of inflammatory rheumatic diseases generally have a diurnal rhythm. Early in the morning, patients experience the most extensive stiffness and other symptoms because of the circadian rhythm of cortisol (see Figure 60-5). In patients with RA who have low or moderate disease activity, serum cortisol maximum and minimum levels shift to earlier times of the day and night, whereas in patients with RA who have high disease activity, the circadian rhythm is markedly reduced or even lost.

The timing of glucocorticoid administration may be important for efficacy and adverse effects. Older data in the literature on this topic were ambiguous.[117,118] More recently, a trial has been performed with a newly developed modified-release prednisone tablet that releases prednisone about 4 hours after ingestion.[119] When it was taken in the evening, thus synchronizing its prednisone release to circadian increases of pro-inflammatory cytokine concentrations, symptoms of RA early in the morning were lessened compared with the symptoms reported when the same dose of prednisone was taken via a normal tablet early in the morning. This 3-month double-blind trial included patients with RA who had a duration of morning stiffness of 45 minutes or longer, a pain score of 30 mm or more on a 100 mm visual analog scale, three or more painful joints, one or more swollen joints, an erythrocyte sedimentation rate (ESR) of 28 mm 1th hour or greater or a C-reactive protein concentration 1.5 times or more the upper limit of normal, and who had been taking glucocorticoids at least 3 months, with a stable daily dose of 2 to 10 mg prednisolone-equivalent for at least 1 month. Patients were randomized in a double-dummy manner to continue their prednisone or to switch to modified-release prednisone. At the end of the trial, the difference in duration of morning stiffness was about 30 minutes in favor of the modified-release prednisone group. No differences were noted in the other clinical variables of disease activity between the two groups. The safety profile did not differ between treatments, and no statistical

difference was found in hypothalamus-pituitary-adrenal axis function.[30,120]

In an open-label observational study among 950 outpatients with RA who were being treated with glucocorticoids and were switching to modified-release prednisone, at assessment 4 months later, improved disease activity was seen.[121] Longer-term benefits and risks of this preparation and application in other inflammatory rheumatic diseases have to be further investigated.[122]

### Other Developments

Deflazacort,[123] an oxazoline derivative of prednisolone introduced in 1969, initially was thought to be as effective as prednisolone while inducing fewer adverse effects, but there is the issue of the real equivalence ratio compared with prednisolone,[124] and deflazacort has not represented a major breakthrough. Knowledge about the mechanisms of glucocorticoids (with the hypothesis that transrepression and transactivation lead, respectively, to predominantly beneficial effects and adverse effects; see earlier) led to the development of selective glucocorticoid receptor agonists.[125] However, the underlying hypothesis was challenged,[15] and the effect of a selective glucocorticoid receptor agonist was disappointing[16]; as yet no such drug has entered the market.

Glucocorticoid preparations releasing nitric oxide, the so-called nitrosteroids, could induce stronger anti-inflammatory effects because nitric oxide also has anti-inflammatory effects.[126] These drugs have yet to be tested in patients.

The drug combination prednisolone and dipyridamole has been reported to boost and extend the net glucocorticoid effect in laboratory models.[127] This synergistic drug, consisting of 3 mg prednisolone and 200 or 400 mg dipyridamole, demonstrated efficacy by statistically reducing pain compared with placebo in persons with osteoarthritis of the hand in a double-blind, placebo-controlled trial and was generally well tolerated.[128] The next required step was to demonstrate an improved therapeutic ratio in patients with other rheumatic diseases in adequate comparative clinical trials by assessing predefined beneficial effects and adverse effects in a standardized manner.[129] After a randomized, double-blind, placebo-controlled, phase IIb clinical trial in RA that showed no meaningful clinical benefit of the synergistic drug compared with prednisolone alone, the development of the synergistic drug has been discontinued.

Liposomes that contain glucocorticoids and are targeted to integrins that are expressed on endothelial cells at sites of inflammation have been studied; these liposomes deliver their glucocorticoids specifically at sites of inflammation.[130] Their selective biodistribution might allow for less frequent and lower dosing, which could result in an improved therapeutic ratio.[131] Clinical studies are needed to see if liposomal glucocorticoids will be effective in clinical rheumatologic practice.

In all, these new glucocorticoid developments, which seemed promising in the past, have not yet lived up to expectations or still must be tested in randomized clinical trials.

Another type of strategy to improve the clinical use of glucocorticoids has been the development of guidelines.[90,132,133]

## ADVERSE EFFECTS AND MONITORING

A toxicity index score for DMARDs based on symptoms, laboratory abnormalities, and hospitalization data of 3000 patients with more than 7300 patient-years from the Arthritis, Rheumatism, and Aging Medical Information System (ARAMIS) database has been published.[134] Although this score has not been validated and is influenced by confounding-by-indication, it gives an impression of the relative toxicity of glucocorticoids. It is comparable with that of other immunosuppressive medications used in persons with RA, such as methotrexate and azathioprine. A review also showed that the incidence, severity, and impact of adverse effects of low-dose glucocorticoid therapy in RA trials were modest and suggested that many of the well-known adverse effects of glucocorticoids probably are predominantly associated with high-dose treatment.[135]

Because many questions remain to be answered, such as how the effect of glucocorticoids compares with that of high dosages of methotrexate or that of TNF blockers and for how long glucocorticoids should be prescribed and in what dosages, the final role of glucocorticoid therapy in RA has yet to be determined. Presently, guidelines on how to use (low-dose) glucocorticoids and how to monitor this therapy have been developed.[132,133]

Given the diversity of their mechanisms and sites of action, it is not surprising that glucocorticoids can cause a wide array of adverse effects (Table 60-6; Figures 60-8 and 60-9). Most of these adverse effects cannot be avoided. However, the risk of most complications is dosage and time dependent, and minimizing the amount of glucocorticoids minimizes the risk of complications.[132] Dose-related patterns of adverse effects of glucocorticoids have been described.[136] Low-dose glucocorticoid therapy is safer than is commonly thought,[135] and medium- to long-term glucocorticoid therapy in persons with RA is associated with limited toxicity compared with placebo,[137] but sensitivity for

**TABLE 60-6** Common Adverse Effects of Glucocorticoids

| System | Adverse Effect |
|---|---|
| Skeletal | Osteoporosis, osteonecrosis, myopathy |
| Gastrointestinal | Peptic ulcer disease (especially in combination with NSAIDs), pancreatitis, fatty liver |
| Immunologic | Predisposition to infections, suppressed delayed hypersensitivity (tuberculin skin test) |
| Cardiovascular | Fluid retention, hypertension, accelerated arteriosclerosis, arrhythmias |
| Ocular | Glaucoma, cataract |
| Cutaneous | Skin atrophy, striae, ecchymoses, impaired wound healing, acne, buffalo hump, hirsutism |
| Endocrine | Cushingoid appearance, diabetes mellitus, changes in lipid metabolism, enhanced appetite and weight gain, electrolyte abnormalities, HPA axis suppression, suppression of gonadal hormones |
| Behavioral | Insomnia, psychosis, emotional instability, cognitive effects |

HPA, Hypothalamic-pituitary-adrenal; NSAIDs, nonsteroidal anti-inflammatory drugs.

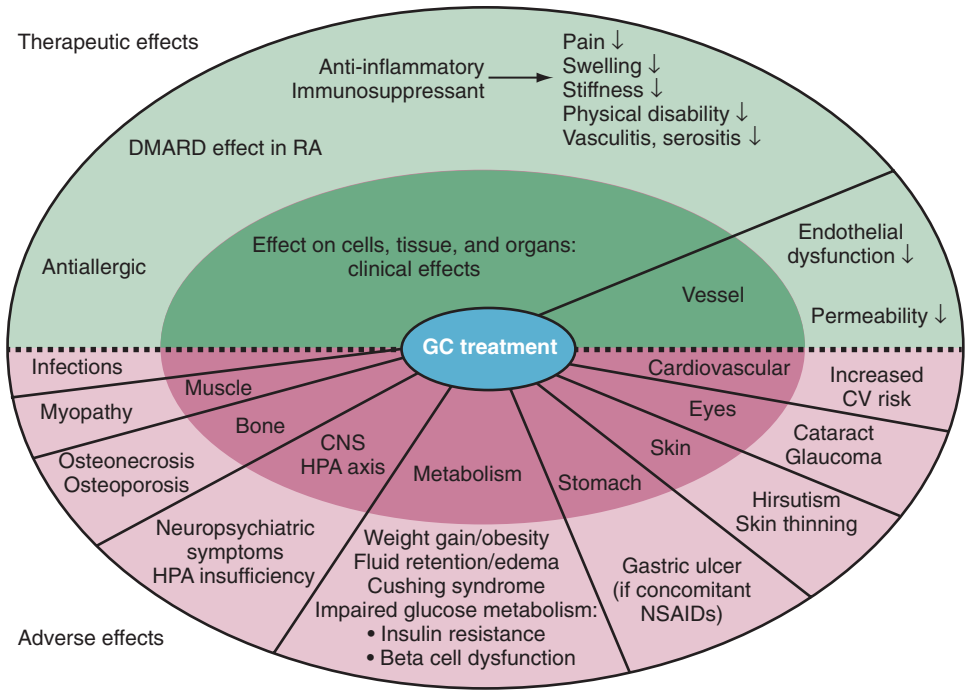

**Figure 60-8** The spectrum of glucocorticoids (GCs) therapy. Beneficial effects are shown in the *green upper part* of the figure, and adverse effects in the *rose-colored lower part*. CNS, Central nervous system; CV, cardiovascular; DMARD, disease-modifying anti-rheumatic drug; HPA, hypothalamic-pituitary-adrenal; NSAIDS, nonsteroidal anti-inflammatory drugs; RA, rheumatoid arthritis. *(Modified from Buttgereit F, Burmester GR, Lipworth BJ: Optimised glucocorticoids therapy: the sharpening of an old spear.* Lancet *365:801-803, 2005.)*

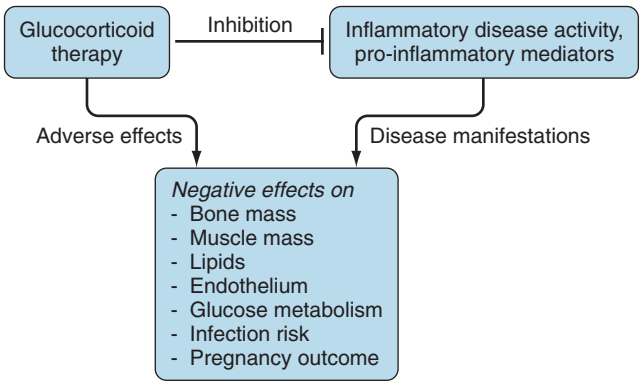

**Figure 60-9** Interplay of glucocorticoid therapy, the inflammatory disease, and negative effects, which can be adverse effects of glucocorticoids and negative effects of the disease itself. Inflammatory diseases have been proven to exert negative effects on bone mass, lipids, endothelium, glucose metabolism and insulin tolerance, infection risk, and pregnancy outcome. These negative effects also are attributed to (especially medium- and high-dose) glucocorticoids. Glucocorticoids suppress the inflammatory disease and thus also these negative disease-related effects.

adverse effects differs for different individuals. Clinical observations indicate some patients experience adverse effects after small doses of glucocorticoids, whereas other patients receive high doses without serious adverse effects. The apparent individual susceptibility to adverse effects does not seem to parallel the individual susceptibility to beneficial effects. Osteoporosis, diabetes, and cardiovascular diseases are ranked among the most worrisome adverse effects of glucocorticoids by both patients and rheumatologists.[138] However, the frequency and severity of glucocorticoid-related adverse effects have seldom been studied systematically. A problem for nonrandomized studies examining glucocorticoid-related adverse effects is bias by indication: Patients with severe disease tend to receive glucocorticoids more frequently than do patients with less severe disease, and both the disease and the glucocorticoids can cause unfavorable signs and symptoms[139]; on the other hand, glucocorticoids decrease disease activity and thus influence the frequency and severity of disease-associated signs and symptoms (see Figure 60-9). Longitudinal data analyses of patients using glucocorticoids at different dosages in time with repeated standardized assessments of disease activity and of other effects would be the best way to disentangle the intricate interaction between glucocorticoids, disease activity, disease-associated signs and symptoms, and glucocorticoid-induced adverse effects.

## Infections

At high doses, glucocorticoids diminish neutrophil phagocytosis and bacterial killing in vitro, whereas in vivo, normal bactericidal and phagocytic activities are found. Monocytes are more susceptible; during treatment with medium to high doses of glucocorticoids, bactericidal and fungicidal activity in vivo and in vitro is reduced. These factors may influence the risk of infection. From epidemiologic studies, treatment with a daily dose of less than 10 mg of prednisolone or its equivalent seems to lead to no risk or only a slightly

increased risk of infection, whereas if doses of 20 to 40 mg daily are used, an increased risk of infection is found (RR 1.3 to 3.6).[140] This risk increases with an increase of the dose and duration of treatment.[141]

In a meta-analysis of 71 trials involving more than 2000 patients with different diseases and who were taking different doses of glucocorticoids, an increased RR of infection of 2 was found. The risk varied according to the type of disease being treated. Five of these trials involved patients with rheumatic diseases and showed no increased risk (RR 1).[140] The same was found in a double-blind, placebo-controlled, 2-year trial in patients with early RA, in which the effect of 10 mg of prednisone daily was compared with that of placebo.[69] In a study, after adjustment for covariates, prednisone use increased the risk of hospitalization for pneumonia in a dose-dependent manner.[141] Another study applying a weighted cumulative-dose model found an elevated risk of serious infections among patients with RA aged 65 years or older, even with chronic low-dose glucocorticoid use; the risk increased with the dosage.[142] In a retrospective RA cohort of patients aged 66 years or older, a clear dose-dependent risk of infections was found, but bias could not be fully excluded, especially because surrogate markers for disease activity had been used as covariates in the analysis.[143] The study suggests, however, that seniors with RA in comparison with younger RA populations may have a higher infection risk related to glucocorticoid use.

Thus in patients treated with glucocorticoids, especially older patients and those who have comorbidities and are taking immunosuppressive co-medications, especially at high doses, clinicians should anticipate infections with usual and unusual organisms because glucocorticoids may blunt classic clinical features and thus delay diagnosis.

## Cardiovascular Adverse Effects

### Mineralocorticoid Effects

Some glucocorticoids also have mineralocorticoid actions (see Table 60-1), including reduced excretion of sodium and chloride and increased excretion of potassium, calcium, and phosphate. This activity may lead to edema, weight gain, increased blood pressure, and heart failure (because of reduced excretion of sodium and chloride); cardiac arrhythmia (because of increased excretion of potassium); or tetany and electrocardiographic changes (as a result of hypocalcemia). Glucocorticoids exhibit no direct effects on kidneys or on renal function.

Low doses of glucocorticoids are not a cause of hypertension, in contrast to higher doses.[144] No formal studies addressing the effects of glucocorticoids in previously hypertensive patients have been reported. Two randomized, controlled studies in patients with myocarditis and idiopathic cardiomyopathy showed no differences between placebo-treated or glucocorticoid-treated groups after 1 year or in survival at 2 and 4 years.[145,146]

### Atherosclerosis and Dyslipidemia

Accelerated atherosclerosis and elevated cardiovascular risk have been reported in patients with SLE, as well as in patients with RA.[147] Glucocorticoids may enhance cardiovascular risk via their potentially deleterious effects on lipids,[148] glucose tolerance, insulin production and resistance, blood pressure, and obesity.[147] Synthetic glucocorticoids have few or no mineralocorticoid effects. In a study, administration of 40 mg prednisone/day did not cause fluid retention, but nevertheless systolic and diastolic blood pressure rose.[149]

However, these risk factors do not seem to be adverse effects of low-dose glucocorticoids. Furthermore, atherosclerosis itself has been recognized as an inflammatory disease of arterial walls,[150] for which glucocorticoids may be beneficial.[151] Glucocorticoids have been found to inhibit macrophage accumulation in injured arterial walls in vitro, possibly resulting in attenuation of the local inflammatory response.[152] Low-dose glucocorticoids might also improve dyslipidemia associated with inflammatory disease.[147,153-155] However, the effects on lipids and other cardiovascular risk factors of low-dose glucocorticoids in inflammatory diseases probably are different from those of medium and high doses of glucocorticoids[148] or of those of glucocorticoid therapy in persons with non-inflammatory diseases. This variation, and the interplay of disease activity, glucocorticoids, and adverse effects (see Figure 60-9), make it difficult to judge the net adverse effects of glucocorticoids on cardiovascular risk and lipids.[156] The finding that a common haplotype of the glucocorticoid receptor gene is associated with heart failure and that this association is partly mediated by low-grade inflammation complicates this issue even more.[157]

In a QUEST-RA study, glucocorticoid use was associated with a decreased risk of cardiovascular morbidity (hazard ratio 0.95; 95% CI, 0.92 to 0.98), but this beneficial effect was smaller than that of other DMARDs.[158] In another study in RA, carotid plaque and arterial incompressibility were associated with glucocorticoid exposure, independently of cardiovascular risk factors and RA clinical manifestations.[159] A literature review showed only a trend of an association in patients with RA between exposure to less than 10 mg/day of prednisone and the risk of major cardiovascular events.[160] In an RA cohort with prospective yearly data assessments, including 779 patients with a total of 7203 patient-years of observation, during which 237 patients died, Cox proportional hazards regression adjusted for potential confounders and for the propensity to receive glucocorticoids was used to assess the hazard ratio of glucocorticoid use for cardiovascular mortality.[161] Compared with no glucocorticoid use, *daily* doses up to 7 mg prednisolone equivalent were not associated with a statistically increased hazard rate; the hazard rate (95% CI) at 8 to 15 mg was 2.3 (1.4 to 3.8), and at 15 mg or more it was 3.2 (1.1 to 9.0). Compared with no glucocorticoid use, *cumulative* doses up to 39 g were not associated with a statistically increased hazard rate; the hazard rate (95% CI) at 40 g or greater was 2.1 (1.3 to 3.3). Compared with no glucocorticoid use, *cumulative* doses *per year* up to 5.07 g were not associated with a statistically increased hazard rate; the hazard rate (95% CI) at 5.08 g or more per year was 2.4 (1.5 to 3.8).

Thus medium and high glucocorticoid doses and long duration of therapy, next to traditional cardiovascular risk factors, including comorbidities such as diabetes mellitus,

inflammatory disease activity, and co-therapies such as COX-2 selective NSAIDs, seem to be the most important cardiovascular risk factors.

## Mortality

In a German biologics register, Cox regression was applied to investigate the impact of time-varying covariates (i.e., disease activity functional disability, treatment with glucocorticoids, and biologic or synthetic DMARDs) on mortality, after adjustment for age, sex, comorbid conditions, and smoking.[162] Disease activity was a clear risk factor for mortality because the risk increased with increasing disease activity. In addition, a dose-dependent risk was seen for glucocorticoid therapy with doses greater than 5 mg prednisone equivalents per day, with an adjusted hazard rate (95% CI) of 1.5 (1.1 to 2.0) for greater than 5 to 10 mg and of 2.0 (1.3 to 3.1) for greater than 10 to 15 mg. Although confounding cannot be fully excluded, similar results have been reported;[163] increased mortality seems to be primarily caused by infections and cardiovascular complications.

## Skeletal Adverse Effects

### Osteoporosis

Osteoporosis is a well-known adverse effect of glucocorticoids; however, the inflammatory disease for which glucocorticoids are given and, especially in inflammatory joint diseases, physical disability and reduced mobility as outcomes of the disease are also risk factors for osteoporosis. Thus glucocorticoids have as adverse-effect, independent of the disease treated, negative effects on bone, but may as therapy for an inflammatory disease have positive effects on bone by suppressing the inflammatory disease and its negative consequences on bone (see Figure 60-10). For instance,

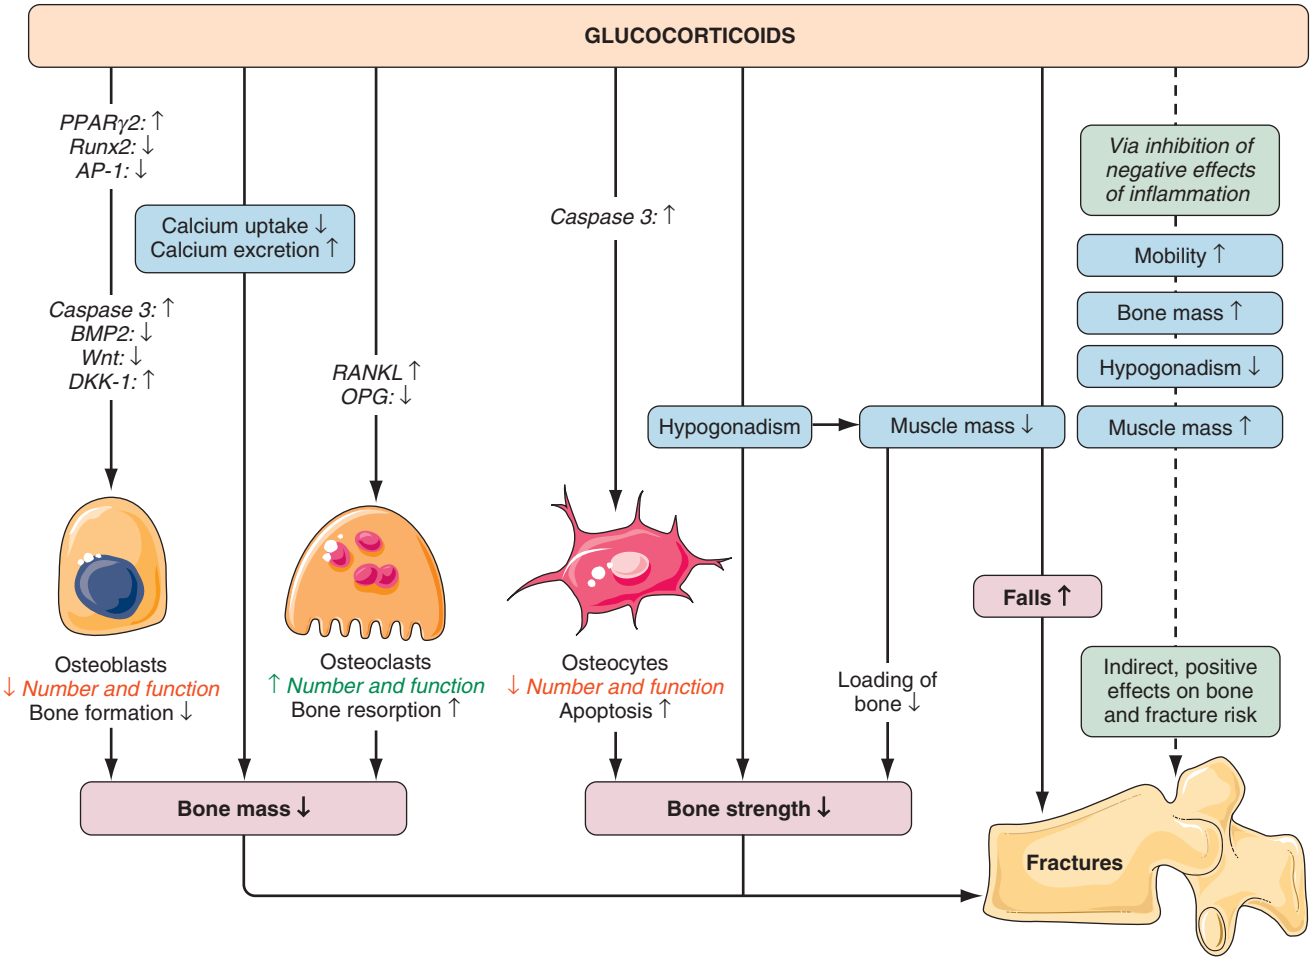

**Figure 60-10** Effects of glucocorticoids on fracture risk: negative effects as adverse effects of this medication and indirect positive effects as therapeutic effects, inhibiting the negative effects of the inflammatory disease.[186-189] AP-1, Activator protein-1 transcription factor complex, including Fos proteins; ↑ increase, stimulation, or upregulation; ↓ decrease, inhibition or downregulation; BMP2, bone morphogenetic protein-2 of the group of BMPs that belong to the transforming growth factor-β superfamily, initiating bone formation; Caspase 3, a critical enzyme for apoptosis and cell survival; DKK-1, dickkopf-1, WNT inhibitor; OPG, osteoprotegerin, the antiosteoclastic decoy receptor for RANKL; PPARγ2, nuclear receptor peroxisome proliferator-activated receptor-γ2 signaling; RANKL, ligand of receptor activator of nuclear factor-κB (RANK), differentiating and activating osteoclasts; Runx2, the Runx2 gene product, stimulating differentiation of mesenchymal cells into osteoblasts; Wnt, Wnt signaling pathway regulating bone homeostasis.

suppressing pro-inflammatory cytokines such as IL-1 and TNF,[83] which stimulate osteoblasts and T cells to produce RANK-ligand, leading to activation of osteoclasts, indirectly has a positive effect on bone mass.

In addition to aromatase inhibitors for breast cancer, androgen deprivation therapy for prostate cancer, and antiepileptic medications,[164] other medications that are associated with a modest increase in fracture risk, especially in elderly persons, and that are not infrequently co-medications of patients taking glucocorticoids, are anti-depressants and proton pump inhibitors (PPIs).[165,166]

The decision whether a patient should be treated depends on fracture risk, effectiveness, safety, and the cost of the treatment. To estimate the risk of fractures for individual patients, several algorithms have been developed, such as the fracture risk in glucocorticoid-induced osteoporosis score (FIGS), which includes the glucocorticoid dosage taken, and fracture risk assessment (FRAX; https://www.shef.ac.uk/FRAX/),[167] for which adjustments also have been suggested for glucocorticoid dosages greater than 7.5 mg prednisone equivalents daily.[168]

To a large degree, osteoporosis can be prevented with calcium and vitamin D supplementation and a biphosphonate if indicated,[169] following national and international guidelines, which are periodically updated.[170,171] Preventive and therapeutic management of glucocorticoid-induced osteoporosis is discussed in another chapter.

### Osteonecrosis

High-dose glucocorticoids for longer periods are implicated as a cause for osteonecrosis, especially in children and patients with SLE. Vascular mechanisms seem to be involved. Ischemia possibly may be caused by microscopic fat emboli or impingement of the sinusoidal vascular bed by increased intraosseous pressure as a result of fat accumulation. An early symptom is diffuse pain, which becomes persistent and increases with activity. Most frequently, hip or knee joints are involved; ankle and shoulder joints are involved less frequently. For early assessment, magnetic resonance imaging is the most sensitive investigation. Radionuclide bone scans give less specific information. Plain radiographs are adequate only for follow-up. Treatment in the early stage includes immobilization and decreased weight bearing. Surgical decompression, joint replacement, or both follow this treatment if needed. There are no preventive measures; awareness is the most important factor in early detection.

### Myopathy

Weakness in proximal muscles, especially of the lower extremities, occurring within weeks to months after the onset of treatment with glucocorticoids or after an increase in the dosage may indicate steroid myopathy. It is often suspected but infrequently found; it occurs almost exclusively in patients treated with high dosages (>30 mg/day prednisolone or its equivalent). Diagnosis is clinical and can be confirmed by a muscle biopsy specimen that reveals atrophy of type II fibers and lack of inflammation; serum muscle enzymes are not elevated. Treatment is withdrawal of the glucocorticoid, if possible, and quite often a prompt decrease in symptoms occurs after withdrawal of the drug. A rare syndrome of rapid-onset, acute myopathy, occurring within days after the start of high-dose glucocorticoids or pulse therapy, has been described; muscle biopsy specimens show atrophy and necrosis of all muscle fibers.

## Gastrointestinal Adverse Effects

### Peptic Ulcer Disease

Data from the literature on upper gastrointestinal safety of oral glucocorticoids are inconclusive. The fact that glucocorticoids inhibit the production of COX-2 without hampering the production of COX-1 supports studies that found no increased risk. In other studies, a RR of serious upper gastrointestinal peptic complications of about 2 was found.[172] When a glucocorticoid is used in combination with an NSAID, the RR of peptic ulcer disease and associated complications is about 4.[173] Thus, in case of co-medication with an NSAID, one should consider co-treatment with a PPI or a switch to a COX-1–sparing NSAID[135] if there is not a high risk of cardiovascular disease (clearly, an inflammatory disease is a moderate risk factor for cardiovascular disease in its own right[150]). In patients treated with glucocorticoids without concomitant use of NSAIDs, there is no indication for gastrointestinal protective agents unless other risk factors for peptic complications are present.

### Other Gastrointestinal Adverse Effects

Although glucocorticoids usually are listed as one of the many potential causes of pancreatitis, evidence for such an association is weak and difficult to separate from the underlying disease, such as vasculitis or SLE.[174] The risk of asymptomatic and symptomatic colonization of the upper gastrointestinal tract with *Candida albicans* is increased in patients treated with glucocorticoids, especially when other risk factors are present, such as advanced age, diabetes mellitus, and concomitant use of other immunosuppressive agents. Glucocorticoids may mask symptoms and signs usually associated with the occurrence of intra-abdominal complications, such as perforation of the intestine and peritonitis, and can lead to a delay in diagnosis with increased morbidity and mortality.

## Ocular Adverse Effects

### Cataract

Glucocorticoids especially tend to stimulate the formation of posterior subcapsular cataract,[175] but the risk of cortical cataract also seems to be increased, with an odds ratio (OR) of 2.6.[176] To some extent, the likelihood or severity of this adverse effect depends on the dose and duration of treatment. In patients treated with glucocorticoids on a long-term basis at a dosage of 15 mg or more of prednisone daily for 1 year, cataract is observed frequently; in patients receiving long-term therapy with less than 10 mg of prednisone daily, the percentage of cataract is less, but cataract may develop at dosages of greater than 5 mg/day of prednisolone equivalent.[136] These cataracts are usually bilateral but

progress slowly. They may cause glare disturbance but usually cause little visual impairment except for end stages.

### Glaucoma

By increasing intraocular pressure, glucocorticoids may cause or aggravate glaucoma. Patients with a family history of open-angle glaucoma are probably prone to the development of this adverse effect, as are patients receiving high doses of glucocorticoids; checks of intraocular pressure are warranted. If ocular pressure is increased, patients need to be treated with medications that reduce this pressure, often for a prolonged period after stopping the glucocorticoid.[177] Topical application of a glucocorticoid in the eye has a more pronounced effect on intraocular pressure compared with systemic glucocorticoid therapy.[178]

## Dermal Adverse Effects

Clinically relevant adverse effects of glucocorticoids on skin include cushingoid appearance, easy bruising, ecchymoses, skin atrophy, striae, disturbed wound healing, acne, perioral dermatitis, hyperpigmentation, facial redness, mild hirsutism, and thinning of scalp hair. Physicians often consider these changes to be of minor clinical importance, but they may be disturbing to patients.[138] No reliable data on the exact frequency of these adverse effects are available, but they are dependent of the duration of therapy and the dose.[136] Many physicians immediately recognize the skin of a patient who has been taking glucocorticoids on a long-term basis.

## Endocrine Adverse Effects

### Glucose Intolerance and Diabetes Mellitus

Glucocorticoids increase hepatic glucose production and induce insulin resistance by inhibiting insulin-stimulated glucose uptake and metabolism by peripheral tissues. Glucocorticoids probably also have a direct effect on the beta cells of the pancreas, resulting in enhanced insulin secretion during glucocorticoid therapy. It may take only a few weeks before glucocorticoid-induced hyperglycemia occurs in persons taking low and medium glucocorticoid doses. In previously nondiabetic subjects, one case-controlled, population-based study suggested an OR of 1.8 for the need to initiate antihyperglycemic drugs during glucocorticoid therapy with doses of 10 mg or less of prednisolone or equivalent per day. This risk increased with higher daily doses of glucocorticoids. The OR was 3 for 10 to 20 mg, 5.8 for 20 to 30 mg, and 10.3 for 30 mg or more of prednisolone or its equivalent per day.[179]

It is likely that the risk is increased further in patients with other risk factors for diabetes mellitus, such as a family history of the disease, advanced age, obesity, and previous gestational diabetes. Postprandial hyperglycemia and only mildly elevated fasting glucose concentrations are characteristic of glucocorticoid-induced diabetes mellitus. Worsening of glycemic control in patients with established glucose intolerance or diabetes mellitus can be expected. Glucocorticoid-induced diabetes usually is reversible when the drug is discontinued, unless the patient had pre-existent clear glucose intolerance.

### Increased Body Weight and Altered Fat Redistribution

Weight gain is an adverse effect of long-term glucocorticoid therapy that is of concern for patients and rheumatologists.[138] Weight gain is due to increased appetite and alterations in fat and glucose metabolism, resulting in an increase of total body and trunk fat. However, weight gain associated with low-dose glucocorticoid therapy for inflammatory diseases seems minor[68,69] and might at least partly also be due to the effectiveness of treatment because active disease has been reported to induce weight loss, possibly as a result of cytokine effects and loss of appetite. In the CAMERA-II trial,[78] the extra weight gain in the prednisone strategy group seemed at least partly attributable to reduction of weight-loss–inducing disease activity, rather than being simply an adverse effect of prednisone.[48] Weight gain in patients with RA who are taking anti-TNF agents seems to be attributable to the same mechanism of efficient suppression of disease activity mechanisms.[180]

One of the most notable effects of long-term endogenous or exogenous glucocorticoid excess is the redistribution of body fat. A centripetal fat accumulation with thin extremities is a characteristic feature of patients exposed to long-term, high-dose glucocorticoids. Potential mechanisms include increased conversion of cortisone to cortisol in visceral adipocytes, hyperinsulinemia, and a change in expression and activity of adipocyte-derived hormones and cytokines, such as leptin and TNF.[181] Protein loss resulting in muscle atrophy also contributes to the change in body appearance.

### Suppression of the Hypothalamic-Pituitary-Adrenal Axis

In the section on effects of glucocorticoids on the HPA axis, mechanisms of chronic suppression of the HPA axis by administration of exogenous glucocorticoids are described. In such a situation, acute discontinuation of glucocorticoid therapy may lead to acute adrenal insufficiency with possible circulatory collapse and death.[27,182] About 10 years after glucocorticoid therapy became available, the first well-documented case of adrenal insufficiency after withdrawal of exogenous glucocorticoid was reported.[183] Acute cessation of glucocorticoid therapy without tapering is indicated for corneal ulceration by herpes virus, which can lead rapidly to perforation of the cornea, and glucocorticoid-induced acute psychosis. In these patients, assessment of the adrenal responsiveness on a corticotropin test seems prudent. Not all patients with a blunted cortisol response have signs or symptoms of adrenal insufficiency, however.

Clinical signs and symptoms of chronic adrenal hypofunctioning are nonspecific and include fatigue and weakness, lethargy, orthostatic hypotension, nausea, loss of appetite, vomiting, diarrhea, arthralgia, and myalgia. These symptoms partially overlap glucocorticoid withdrawal symptoms, such as fatigue, arthralgia, and myalgia. When in doubt, measurements of serum cortisol levels and the corticotropin stimulation test are indicated. The glucocorticoid withdrawal symptoms also are sometimes difficult to discriminate from the symptoms of the primary disease, such as polymyalgia rheumatica. Because mineralocorticoid secretion remains intact via the renin-angiotensin-aldosterone

axis, electrolyte disturbances such as hypokalemia are uncommon.

## Adverse Behavioral Effects

Glucocorticoid treatment is associated with a variety of behavioral symptoms. Although most attention has been directed toward specific dramatic disturbances collectively described under the term *glucocorticoid psychosis*, less florid effects also occur that may cause distress to a patient and warrant medical attention.[138] Minor behavioral manifestations may also occur upon withdrawal of glucocorticoids.

### Steroid Psychosis

Overt psychosis is rare and usually is associated with high-dose glucocorticoids or glucocorticoid pulse therapy, but psychosis also may be a complication of the disease itself, especially SLE. This situation makes it difficult to distinguish whether psychosis in an individual patient with SLE is a complication of the disease, the therapy, or both.

Isolated psychosis represents about 10% of glucocorticoid-related cases, but in most patients, affective disorders are present as well. Around 40% of cases of glucocorticoid-induced psychosis manifest as depression, whereas mania, often dominated by irritability, is predominant in 30% of cases.[184] Psychotic symptoms usually start just after initiation of treatment (60% within the first 2 weeks and 90% within the first 6 weeks), and remission after drug dose reduction or withdrawal follows the same pattern. Although the data are largely anecdotal, persons experiencing steroid psychosis frequently have had prior evidence of some dissociative symptoms. Occasionally, remission occurs without dose reduction.

### Minor Mood Disturbances

Glucocorticoids have been associated with a wide variety of low-grade disturbances, such as depressed or elated mood (euphoria), insomnia, irritability, emotional instability, anxiety, memory failure, and other cognition impairments. Although the symptoms may not become severe enough for a specific diagnosis, they warrant attention—not only because they cause distress to the patient, but also because they may interfere with evaluation and treatment of the underlying disease. Most physicians recognize the occurrence of such symptoms in many patients treated with glucocorticoids; these symptoms may occur in varying degrees in up to 50% of treated patients within the first week. The exact incidence in patients with rheumatic disease who are exposed to the usual doses of glucocorticoids is unknown; most series dedicated to mood disturbances studied high doses.[185] It is important to inform patients about these minor mood disturbances before starting glucocorticoid therapy.[138]

## Monitoring

Glucocorticoid-related adverse effects have seldom been studied systematically. Mostly on the basis of expert and patient opinion, recommendations have been formulated to monitor low-dose glucocorticoid therapy. The conclusion is that, in daily practice, standard care monitoring for serious diseases warranting glucocorticoid therapy need not be extended for patients undergoing low-dose glucocorticoid therapy, except for osteoporosis (for which national guidelines should be followed) and baseline assessments of fasting blood glucose and risk factors for glaucoma, next to a baseline check for ankle edema.[133] Of course, monitoring should be extended for medium and high dosages, not only to monitor for adverse effects of the glucocorticoid therapy, but also for adverse effects of the concomitant medication and complications of the severe disease. For these glucocorticoid dosages, no monitoring guidelines yet exist, but there are recommendations on the management of medium to high-dose glucocorticoid therapy in rheumatic diseases.[90] In these situations, next to good clinical practice monitoring including, for instance, blood pressure measurements, checks of ocular pressure and urine glucose in particular seem to be indicated. When performing clinical trials on glucocorticoids, it is advised that these drugs be monitored and reported in a more comprehensive manner and that more data on the spectrum, incidence, and severity of adverse events of glucocorticoids be sampled.[133] When applied prudently, glucocorticoids are still one of the most relevant therapeutic tools in clinical medicine of the 21st century.

# FUTURE DIRECTIONS

Although biologic therapies are applied frequently in rheumatology, they have not replaced—and in the near future will not replace—glucocorticoids as anchor drugs in therapeutic strategies for autoimmune and inflammatory diseases and vasculitides. In contrast to their established use, there is a paucity of data on the spectrum, incidence, and severity of the adverse effects of glucocorticoids at different dosages and in different diseases, and collection of more data is needed.[133] Additional research into molecular mechanisms and genetic developments might in the future lead to new agents and personalized medicine,[4] but it appears that these developments still have a long way to go. With the exception of modified-release prednisone, new glucocorticoid developments that seemed promising in the past have not yet lived up to expectations or still need to be tested in randomized clinical trials.

CHAPTER 61

# Traditional DMARDs: Methotrexate, Leflunomide, Sulfasalazine, Hydroxychloroquine, and Combination Therapies

Amy C. Cannella • James R. O'Dell

**KEY POINTS**

- Methotrexate is one of the most durable and frequently used disease-modifying anti-rheumatic drugs (DMARDs) in monotherapy as well as the cornerstone of combination therapy for rheumatoid arthritis (RA).
- Leflunomide, sulfasalazine, and hydroxychloroquine are effective therapies in RA and are commonly used in combination therapy.
- Although the precise mechanisms of action of the traditional DMARDs are incompletely understood, most have both anti-inflammatory and immunomodulatory actions.
- The choice of DMARD therapy should be tailored to the individual patient, with attention given to age, fertility plans, concomitant medications, and comorbidities.
- Toxicity from DMARD therapy can cause significant morbidity and rarely mortality; thus appropriate dosing and monitoring for toxicity are essential.
- Combination therapy in RA can be more effective than mono-DMARD therapy in groups of patients with early-stage and established RA.
- The appropriate timing and combinations of DMARD therapy in individual patients is still not defined.

## METHOTREXATE

**KEY POINTS**

- An important mechanism of action for methotrexate (MTX) in addition to blocking dihydrofolate reductase is the increased release of of adenosine, which is a potent inhibitor of inflammation.
- MTX is polyglutamated in cells, and this is responsible for its long therapeutic effect.
- The effects of MTX may be enhanced by splitting the dose (within a 12-hour window) when levels greater than 15 mg/wk are used, or by using a subcutaneous route of administration.
- Combined use of folic acid with MTX abrogates some of the side effects of MTX without decreasing its efficacy.
- The dose of MTX must be adjusted for reduced renal function.
- Although rare, MTX pneumonitis is a serious and potentially fatal complication of therapy.

It would be difficult to overstate the importance of methotrexate (MTX) in the contemporary management of rheumatic disease and, in particular, rheumatoid arthritis (RA). Because of its anti-proliferative effects, MTX was introduced more than 50 years ago to treat cancer. During the last quarter century, it has become the disease-modifying anti-rheumatic drug (DMARD) of choice in the treatment of RA and is used to treat many other rheumatic diseases as well.

### Chemical Structure

MTX is a structural analogue of folic acid and has substitutions in the pteridine group and para-aminobenzoic acid structure (Figure 61-1). The structure of folic acid (pteroylglutamic acid) consists of three elements: a multiring pteridine group, linked to a para-aminobenzoic acid, which is connected to a terminal glutamic acid residue.

### Actions of Methotrexate

Because MTX is a folate analogue, it enters cells via a reduced folate carrier (RFC). Leucovorin competes with MTX for uptake by using the same RFC; however, folic acid enters cells via another group of transmembrane receptors called *folate receptors* (FRs).[1] FRs may be upregulated in cells with increased metabolic activity, including synovial macrophages, and serve as a second conduit for MTX influx.[2,3] MTX efflux occurs via members of the adenosine triphosphate (ATP)-binding cassette (ABC) family of transporters, specifically ABCC1-4 and ABCG2.[4] Genetic polymorphisms may affect MTX transporter proteins (influx and efflux) and can result in a variable MTX response and toxicity profile.[4] Furthermore, multidrug-resistance proteins have been identified that transport MTX, folic acid, and leucovorin out of cells, leading to MTX resistance.[5]

Once inside the cell, naturally occurring folates as well as MTX undergo polyglutamation by the enzyme folylpolyglutamyl synthetase (FPGS). Polyglutamation of MTX (MTX-PG) is essential to prevent efflux of MTX, which easily occurs in the monoglutaminated state. MTX-PG has several key inhibitory effects on intra-cellular enzymes, which result in its postulated anti-inflammatory and anti-proliferative (immunosuppressive) mechanisms: (1) inhibition of aminoimidazole carboxamide ribonucleotide (AICAR) transformylase (ATIC) results in increased intracellular and extra-cellular adenosine, (2) inhibition of thymidylate synthetase (TYMS) results in decreased pyrimidine

synthesis, and (3) inhibition of dihydrofolate reductase (DHFR) results in inhibition of transmethylation reactions essential for cellular functioning (Figure 61-2).

Inhibition of ATIC by MTX-PG leads to accumulation of AICAR and, ultimately, to increased levels of adenosine. Three possible mechanisms are postulated and likely work in combination: (1) AICAR inhibition of adenosine monophosphate (AMP) deaminase leads to excess production of adenosine from AMP, (2) AICAR inhibition of adenosine deaminase (ADA) leads to decreased breakdown of adenosine to inosine, and (3) AICAR stimulation of the ecto-5′-nucleotidase converts extra-cellular AMP to adenosine[6-8] (Figure 61-3).

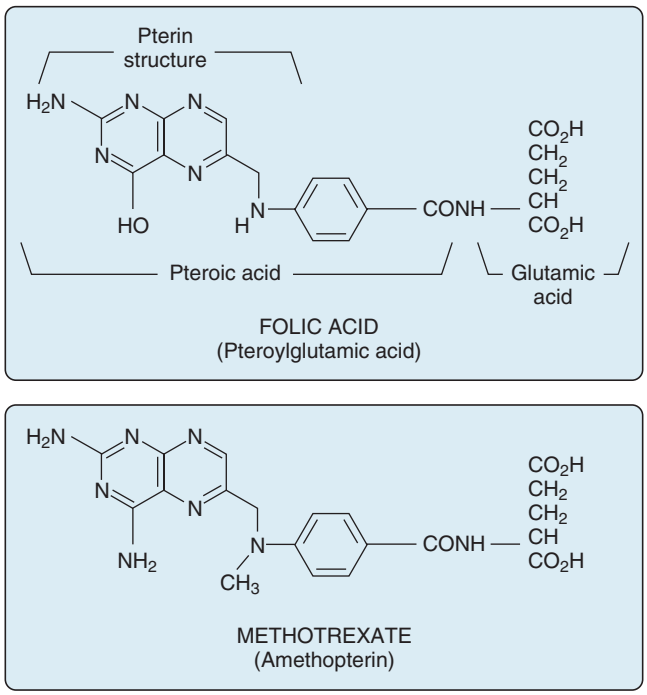

**Figure 61-1** Chemical structure of folic acid and methotrexate.

Adenosine, a purine nucleoside, has been termed a "retaliatory metabolite" because of its tissue protective functions after stressful injurious stimuli.[9] Adenosine, a potent inhibitor of inflammation,[9] induces vasodilation.[10,11] Adenosine's anti-inflammatory effects include regulation of endothelial cell inflammatory functions, including cell trafficking,[10,11] counter-regulation of neutrophils and dendritic cells,[9,12] and cytokine modulation of monocytes and macrophages.[9] Adenosine receptor ligation on monocytes and macrophages suppresses interleukin (IL)-12, a strong pro-inflammatory cytokine.[13] Adenosine also suppresses the pro-inflammatory mediators TNF, IL-6, IL-8, macrophage inflammatory protein (MIP)-1α, leukotriene $(LT)B_4$, and nitric oxide and enhances production of the anti-inflammatory mediators IL-10 and IL-1 receptor antagonist.[14-19] Furthermore, adenosine receptor–mediated processes result in inhibition of the synthesis of collagenase, including tissue inhibitors of metalloproteinases.[20] In sum, adenosine appears to promote a self-limiting, healthy immune response, hastening the transition from neutrophil-mediated inflammation to a more efficient and highly specific dendritic cell–mediated response. Ultimately, adenosine leads to the resolution of inflammation by downregulation of macrophage activation and promotes a shift from a T helper (Th)1 cell to a Th2 cell response.[9]

Evidence that the anti-inflammatory effects of MTX are mediated through adenosine has accumulated in in vitro and in animal studies.[21] However, because of adenosine's short blood half-life of 2 seconds and MTX's long latent period for active metabolites that modulate adenosine, it has been difficult to demonstrate changes in blood adenosine levels directly related to MTX.[22] Recent evidence with use of forearm blood flow as a surrogate marker for

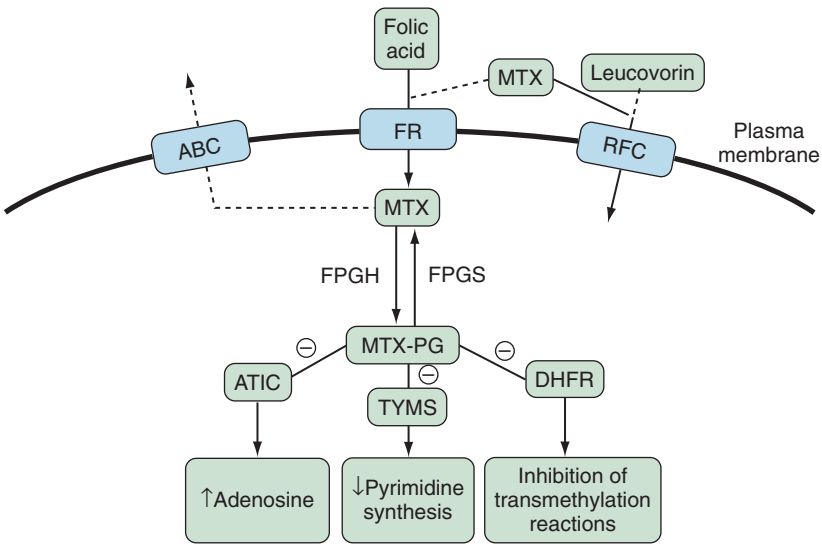

**Figure 61-2** Methotrexate (MTX) enters cells primarily via the reduced folate carrier (RFC) but can use the folate receptor (FR). Once inside the cell, it becomes polyglutamated and can interfere with several cellular enzymes, including 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase (ATIC), thymidylate synthetase (TYMS), and dihydrofolate reductase (DHFR). ABC, ATP-binding cassette; FPGH, folylpolyglutamate hydrolase; FPGS, folyl-polyglutamyl synthetase; MTX-PG, polyglutamation of MTX.

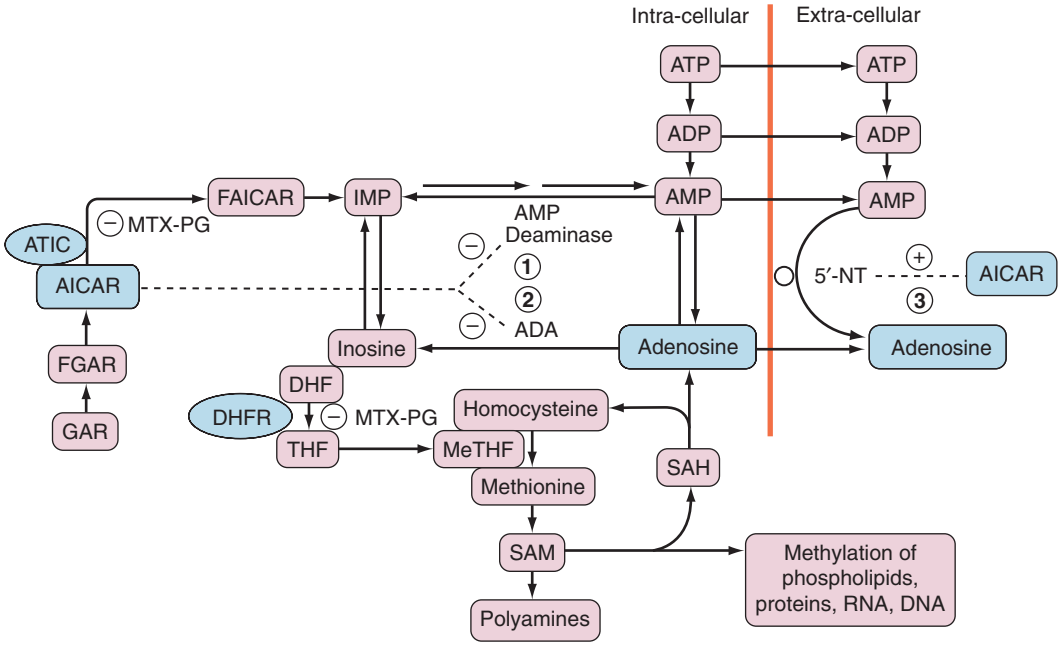

**Figure 61-3** Simplified schema of the effects of polyglutamation of methotrexate (MTX-PG) on intra-cellular and extra-cellular adenosine production and interference with intra-cellular transmethylation reactions. ADA, Adenosine deaminase; ADP, adenosine diphosphate; AICAR, 5-aminoimidazole-4-carboxamide ribonucleotide; AMP, adenosine monophosphate; ATIC, aminoimidazole carboxamide ribonucleotide transformylase; ATP, adenosine triphosphate; DHF, dihydrofolate; DHFR, dihydrofolate reductase; FAICAR, formyl-AICAR; FGAR, α-*N*-formylglycinamide ribonucleotide; GAR, β-glycinamide ribonucleotide; IMP, inosine monophosphate; MeTHF, methyltetrahydrofolic acid; 5′NT, 5′-nucleotidase; SAH, *S*-adenosylhomocysteine; SAM, *S*-adenosylmethionine; THF, tetrahydrofolate.

adenosine release in patients with RA treated with MTX demonstrated that MTX inhibits deamination of adenosine and potentiates adenosine-induced vasodilation.[23] Demonstration of altered adenosine kinetics in patients treated with MTX coupled with adenosine's known anti-inflammatory effects lends further credence to the hypothesis that MTX increases extra-cellular adenosine, which likely mediates some of the anti-inflammatory effects of MTX.

In addition to vasodilation, adenosine's cardiovascular effects include negative inotropic and chronotropic cardiac effects, inhibition of vascular smooth muscle cell proliferation, pre-synaptic inhibition of sympathetic neurotransmitter release, and inhibition of thrombocyte aggregation.[24] Patients with RA have a higher incidence of cardiovascular disease than the general population.[25] MTX has been suggested to have a preferentially beneficial effect on cardiovascular mortality compared with other DMARDs in RA, and this effect likely occurs via adenosine modulation.[26]

The anti-inflammatory and anti-proliferative effects of MTX may be mediated through its inhibition of transmethylation reactions. Both MTX and MTX-PG inhibit DHFR, resulting in diminution of tetrahydrofolate (THF). THF acts as a proximal methyl donor for several reactions by donating the methyl group for the conversion of homocysteine to methionine. Methionine is then converted to *S*-adenosylmethionine (SAM), which acts as a methyl donor for the following: methylation of RNA, DNA, amino acids, proteins, and phospholipids, and synthesis of the polyamines spermidine and spermine. Upon demethylation of SAM to *S*-adenosylhomocysteine (SAH), SAH is converted to adenosine and homocysteine. Methylation products that are dependent upon SAM, and thus indirectly upon DHFR, to generate THF are required for cellular survival and function, although specific cellular dependence upon each varies[17] (see Figure 61-3).

The role of polyamines deserves further discussion. Spermine and spermidine accumulate in urine,[27] in peripheral blood mononuclear cells,[28] and in synovial fluid and tissue[29] in patients with RA. Metabolism of polyamines by mononuclear cells gives rise to toxic agents, including ammonia and hydrogen peroxide, which may impair lymphocyte function.[30,31] Additionally, accumulation of polyamines in B cells is associated with enhanced production of rheumatoid factor (RF) in vitro, and incubation of these cells with MTX diminishes their ability to secrete both immunoglobulin and RF.[17] These effects are seen with high in vitro concentrations of MTX and may not translate into the in vivo therapeutic effects of MTX in RA.

In addition, MTX inhibits methylation of 2′-deoxyuridylate (dUMP) into 2′-deoxythymidylate (dTMP) by TYMS, resulting in a further mechanism for disruption of DNA synthesis and proliferation of inflammatory cells. This effect has been shown in vitro in human peripheral blood mononuclear cells incubated with low concentrations of MTX.[32] Cell cycle disruption may lead to apoptosis of mononuclear cells via CD95 (APO-1/Fas) ligand-dependent[33] and ligand-independent mechanisms.[34]

Therefore inhibition of transmethylation reactions may lead to MTX efficacy via anti-proliferative and anti-inflammatory mechanisms. Disruption of DNA, RNA,

amino acid, and phospholipid synthesis results in its anti-proliferative effect, which may be mediated via cellular apoptosis. Decreased levels of polyamines may downregulate the production of toxic agents, as well as RF secretion, leading to its anti-inflammatory effect.

In theory, the anti-inflammatory and anti-proliferative properties of MTX already described should make it a potent inhibitor of the immune response that characterizes many rheumatic diseases. Indeed, MTX has become the cornerstone of therapy for RA and is efficacious in multiple other rheumatic diseases. Direct evidence for the immunomodulatory effects of MTX exists, whether studied in in vitro or in vivo systems.

Treatment with MTX modulates monocytic and lymphocytic cytokines and their inhibitors. MTX inhibits pro-inflammatory cytokine IL-1 secretion and to induce the IL-1 receptor antagonist, effectively inhibiting cellular responses to IL-1.[35,36] Soluble TNF receptor (sTNFR p75) synthesis upregulation is also a result of MTX treatment from cultured monoblastic leukemia cells, which results in a diminished TNF inflammatory effect.[37] MTX also inhibits production and secretion of the pro-inflammatory cytokine, IL-6, by cultured human monocytes.[38,39] Reverse transcriptase polymerase chain reaction has been used to study the effects of MTX on gene expression for lymphocytic cytokines.[40,41] MTX increases anti-inflammatory Th2 cytokine (IL-4 and IL-10) gene expression and decreases pro-inflammatory Th1 cytokine (IL-2 and IFN-γ) gene expression in peripheral blood mononuclear cells (PBMCs) of patients with RA.[41]

Prostaglandins (PGs) and LTs are important mediators of joint destruction in RA. MTX modulates the inflammatory enzymes cyclooxygenase (COX) and lipoxygenase (LOX), and their products PG and LT. Thromboxane $B_2$ and prostaglandin $E_2$ activities were reduced in the whole blood of patients with RA treated with MTX when compared with healthy controls.[42] MTX also reduces $LTB_4$ synthesis by neutrophils, resulting in a decrease in total plasma $LTB_4$ levels in patients with RA treated weekly with MTX.[43] In addition to possible direct effects on COX and LOX, MTX exerts an inhibitory effect on neutrophil chemotaxis, which may result in a further reduction of these enzymes in sites of inflammation.[44]

Tissue destruction at sites of inflammation is thought to be related to increased synthesis and activity of proteolytic enzymes released by inflammatory cells, particularly in RA. MTX treatment reduces gene expression of collagenase, metalloproteinase-1, and stromelysin, and to upregulate expression of tissue inhibitor of metalloproteinase (TIMP)-1.[45] MTX may exert direct effects on messenger RNA (mRNA) for certain enzymes, such as collagenase. MTX also likely exerts indirect effects on gene expression via upstream cytokine modulation (IL-1 and IL-6), in the case of matrix metalloproteinase (MMP)-1 and TIMP-1.[46]

## Pharmacology

### Absorption and Bioavailability

At low doses, MTX can be administered either orally or parenterally (subcutaneous [SQ] or IM), and absorption is rapid, peaking at 1 to 2 or 0.1 to 1 hour, respectively. The absorption of low-dose oral MTX (<15 mg/wk) can be variable, and once the oral dose exceeds 15 mg/wk, absorption diminishes by as much as 30%.[47] Absorption is not reduced by concomitant food intake, except for milk, which may be inhibitory,[48] but may be reduced in the setting of intestinal pathology, such as inflammatory bowel disease or malabsorptive conditions.

Orally administered MTX is absorbed via the gastrointestinal (GI) tract and passes through the liver via the portal vein; parenterally administered MTX passes through the liver via the hepatic artery. Parentally administered MTX has higher systemic levels attained compared to orally administered MTX at equal dosing intervals. In addition, the bioavailability of single dose daily oral MTX plateaus at doses of 15 mg/week, whereas parenteral MTX has a linear increase in systemic levels with increasing dosages.[49] Higher systemic levels have not been associated with any increase in toxicity.[49,50] Although not prospectively studied in RA patients receiving long-term MTX treatment, the parenteral route should have diminished potential for hepatotoxicity. This effect has been seen in a retrospective study wherein more elevations in transaminases were noted when oral MTX was administered to the same individuals versus when given parenterally.[51] A recent study at equivalent MTX doses showed improved efficacy in RA clinical endpoints for parenteral versus orally administered MTX.[52]

Forty-one RA patients who received 10 mg/m$^2$ of oral MTX had a mean bioavailability of 70% with a range of 40% to 100%.[53] The mean absorption time was 1.2 hours. Four hours after MTX administration, synovial fluid concentrations equal serum levels.[53] A recent study of high-dose oral MTX (median dose, 30 mg/wk) has shown that mean bioavailability is improved by splitting the dose by 8 hours compared with one single dose (mean bioavailability of 0.9 and 0.76, respectively).[54] The pharmacokinetics of subcutaneous MTX are equivalent to those of intramuscular (IM) MTX; maximum serum concentration is attained within 2 hours of injection by either route.[55] Also, the bioavailability is equivalent between tablets and orally administered parenteral solution.[56]

### Distribution and Half-Life

MTX is 50% to 60% bound to plasma proteins and has a half-life of approximately 6 hours.[53] An increase in free MTX caused by displacement from albumin by more highly protein-bound drugs, such as aspirin, NSAIDs, and sulfonamides, can occur. This is generally of limited clinical significance with low MTX doses because the increase in free MTX is usually only modest.

MTX accumulates in third-space fluids, which can serve as a reservoir for redistribution into the circulation long after the last dose is administered.[57] Caution should be used when administering MTX to patients with pleural effusions or ascites. Furthermore, unexpectedly high levels of MTX have been seen in patients with bladder cancer who have undergone ileal conduit surgery because of enhanced intestinal absorption through the newly fashioned conduit.[58]

The biologically active form of MTX occurs after intracellular polyglutamation (MTX-PG). MTX undergoes up to five polyglutamations, and recent studies have looked at this aspect of MTX pharmacology. Once on a stable dose of

MTX, the median time until 90% of the maximum steady-state concentration of MTX-PG was reached was found to be 27.5 weeks (range, 6.6 to 62.0 weeks).[59]

### Elimination

Most MTX is excreted in the urine within the first 12 hours after administration, except for MTX-PG. MTX undergoes some hepatic metabolism by the enzyme aldehyde oxidase to the 7-hydroxymethotrexate metabolite; this metabolite has unknown significance in RA. MTX and metabolites are excreted by the kidney by glomerular filtration and proximal tubular secretion but also undergo distal tubular reabsorption. The estimated median half-life of elimination of MTX-PG is 3.1 weeks (range, 0.94 to 4.1 weeks), and MTX-PG is undetectable at 15 weeks.[59] $MTX\text{-}PG_3$ is the most common subtype seen (30% of total MTX-PG) and has a median half-life elimination of 4.1 weeks.

### Indications

**Rheumatoid Arthritis.** The efficacy of MTX in RA has been clearly established. Four well-designed, blinded, placebo-controlled trials[60-63] published in 1984 and 1985 had a tremendous impact on the treatment of RA. These trials varied in design and duration: Two of these trials used oral MTX and two used IM MTX, two trials had a crossover and two were parallel, and the duration of treatment varied from 6 to 28 weeks. Although the design and duration of therapy in these trials varied, the conclusions did not, as all showed MTX to be superior to placebo in the short-term treatment of RA. A meta-analysis of these trials by Tugwell and co-workers[64] showed that MTX-treated patients had a 37% greater improvement in swollen joint and tender joint scores, a 39% greater improvement in joint pain, and a 46% greater improvement in morning stiffness. MTX was generally well tolerated in these trials; withdrawal rates ranged from 0 to 32% and were mostly related to minor toxicities (i.e., stomatitis and nausea). Taken together, the results of these trials firmly established MTX as an effective therapy for the treatment of RA, at least in the short term.

Numerous trials have compared MTX with other DMARDs. A meta-analysis done by Felson and co-workers showed that MTX was superior to placebo, auranofin, and probably hydroxychloroquine (HCQ), and was comparable with penicillamine, sulfasalazine (SSZ), and IM gold.[65] No trial has ever suggested that any other synthetic DMARD is superior to MTX.

Accumulating evidence suggests that the short-term benefit of most DMARDs is not sustained, and few patients continue to take these drugs after 3 years.[66,67] MTX appears to have the best durability. Pincus and colleagues have shown that 60% of patients continued MTX at 5 years, compared with less than 25% for penicillamine, gold, HCQ, and azathioprine.[66] Of all the DMARDs, MTX appears to have the best efficacy-to-toxicity ratio.[65] However, despite all the favorable efficacy reports, MTX alone rarely induces remissions of RA, and it has become the cornerstone of combinations of DMARD therapies as discussed later.[68,69]

**Rheumatoid Arthritis–Related Conditions.** MTX has been used successfully in treating Felty's syndrome[70] and the large granular lymphocyte syndrome when it is found in patients with RA.[71] Improvement in neutrophil count occurs within 4 to 8 weeks of MTX initiation in both cases. MTX has been used successfully in adult-onset Still's disease[72] and for the cutaneous vasculitis of RA.[73]

**Juvenile Idiopathic Arthritis.** MTX is efficacious in juvenile idiopathic arthritis. A definitive, randomized, placebo-controlled trial (RCT) demonstrated that MTX at a dose of 10.0 $mg/m^2$ was superior to 5.0 $mg/m^2$ or placebo.[74] Sixty-three percent of children receiving the higher dose (10.0 $mg/m^2$) of MTX improved, compared with 32% in the lower-dose group (5.0 $mg/m^2$) and 36% in the placebo group.

**Psoriatic Arthritis (PsA).** Numerous prospective and retrospective trials have showed a benefit for MTX in PsA.[75] The largest double-blind randomized trial compared weekly oral MTX with placebo and showed statistically significant results only for physician global assessment of arthritis activity and the amount of affected skin surface area; however, this study was small and may have been underpowered to detect differences in joint count, pain, and swelling.[76] Despite the paucity of randomized controlled trial data, MTX remains a commonly used systemic agent in the treatment of PsA.

**Systemic Lupus Erythematosus (SLE).** MTX is efficacious in controlling cutaneous and/or articular manifestations of SLE, particularly in disease resistant to anti-malarials or requiring high doses of systemic steroids.[77] Concomitant folic acid should be administered to abrogate the elevated levels of homocysteine that may be a side effect of MTX therapy and is considered a risk factor for cardiovascular disease in SLE. The role of MTX in treating more severe SLE involvement, including renal, hematologic, or central nervous system (CNS) disease, has not yet been established.[78] Extreme caution should be used in patients with renal disease.

**Vasculitis.** MTX in conjunction with corticosteroids is efficacious in treating early and non–life-threatening granulomatosis with polyangiitis, including upper airway disease and mild renal disease.[79-82] In addition to induction of remission, MTX maintains remission in granulomatosis with polyangiitis, although physician vigilance for patient relapse is warranted.[83] Despite a lack of well-designed studies, MTX has been shown to be efficacious in corticosteroid-resistant Takayasu's arteritis[84] and in relapsing polychondritis.[85]

The use of MTX for polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) has been controversial. Recently, RCTs of MTX in addition to corticosteroids in PMR and GCA have shown conflicting results.[86-89] Thus the routine use of MTX in either PMR or GCA has not been adopted, but some advocate for its use in an effort to more rapidly taper corticosteroid use in patients with intolerable side effects.

**Inflammatory Myopathies.** A review of the published reports of MTX and the inflammatory myopathies polymyositis (PMS) and dermatomyositis (DMS) shows overall positive results.[90] However, despite the frequent use of MTX in the inflammatory myopathies, a recent Cochrane Database Review reveals a paucity of well-designed trials.[91]

**Other Rheumatic Diseases.** MTX has been used in systemic sclerosis. One RCT looking at MTX use in early systemic sclerosis[92] showed a trend in benefit for skin scores

and pulmonary diffusion capacity and a significant benefit for physician global assessment; a second RCT in established systemic sclerosis[93] showed significant benefit for skin scores and total creatinine clearance. In addition, prospective trials have shown that MTX is efficacious in the treatment of corticosteroid-resistant multisystem sarcoidosis,[94,95] and a recent RCT showed that, if initiated early in sarcoidosis, MTX is an effective steroid-sparing agent.[96] MTX is also effective as primary treatment and as a corticosteroid-sparing agent in inflammatory ocular disease.[97,98] Finally, MTX in combination with corticosteroids is effective in the treatment of multicentric reticulohistiocytosis.[99]

## Dose and Drug Administration

MTX is available as 2.5, 5, 7.5, 10, and 15 mg tablets, and as a solution of 25 mg/mL for SQ or IM injection. Recently, the U.S. Food and Drug Administration (FDA) has approved single- and multiple-use, pre-filled autoinjection pens at various dosages.

The starting dose is usually 15 mg given as a single weekly dose, with a range of 5 to 25 mg weekly, and consideration should be given to initiation via the parenteral route for improved efficacy. More frequent administration is associated with a significantly increased risk of liver toxicity.[100] If the oral dose of MTX exceeds 15 mg, consideration should be given to splitting the dose, with each half given 6 to 12 hours apart, for improved absorption and bioavailability. The dosage of MTX can be escalated, usually every 4 to 8 weeks to 25 mg/wk to achieve the desired clinical response. MTX may be administered orally via tablet or parenteral solution; the latter may be less costly. Because its oral bioavailability is variable and decreases at higher doses, parenteral MTX is generally recommended if patients have active disease despite oral doses at approximately 20 mg weekly. In fact, recent data have shown that parenteral MTX is clinically superior to orally administered MTX, and that this may be a preferred route of administration, for initial therapy[101] or if oral MTX is not optimally effective.[52]

Because MTX works by interfering with folate-dependent pathways, a relative folate-deficient state can occur in individuals taking MTX. Concomitant administration of folic acid or folinic acid (<7 mg/week) decreases the frequency of MTX side effects, including GI toxicity (nausea, vomiting, abdominal pain) and stomatitis. Supplementation of folic or folinic acid is protective against elevated transaminase concentrations, results in fewer toxicity-related withdrawals of MTX, and does not interfere with the efficacy of MTX.[102] Folic acid administration also decreases hyperhomocysteinemia in patients on MTX, and this may be important to help decrease the already high cardiovascular risk of patients with RA. There is insufficient evidence to suggest that one form of folate has clinical advantages versus the other, and because folic acid is widely available and less expensive, it has become the preferred agent for most.[102]

Measurement of MTX-PG levels is commercially available ($MTXGlu_n$). It would be valuable to have a marker to predict response and adverse events associated with MTX therapy, but mixed results have been obtained in the search for a trend in the dose-response relationship for $MTXGlu_n$ levels and RA disease activity. A recent study showed no relationship between $MTXGlu_n$ concentration and reduced disease activity in RA.[103] Furthermore, no relationship was identified between $MTXGlu_n$ levels and adverse events. Disease activity was influenced by red blood cell (RBC) folate level, and further study is warranted to determine whether this may serve as a marker for MTX efficacy.

### Geriatric Patients

Patients older than 65 years represent a special subset of patients receiving pharmacotherapy. Pharmacokinetic profiles, including drug distribution, are changed in the elderly as the result of decreases in end-organ blood flow and lean body mass, decreased hepatic drug metabolism, and decreased renal drug excretion. Furthermore, these patients are more likely to have multiple comorbidities, polypharmacy, noncompliance, increased risk for dosage errors, and limited access to medication for financial reasons.[104]

In practice, recommended doses should be reduced when therapy is initiated and should be adjusted for renal function based on creatinine clearance (CrCl).[105] The serum creatinine may be a misleading measure of renal function in older patients because of an overall reduction in lean muscle mass. Dosing recommendations are as follows: initial doses should be approximately 5 to 7.5 mg/wk and should not exceed 20 mg/wk. Dosage adjustments for CrCl are as follows: for a CrCl of 61 to 80 mL/min, reduce the dose by 25%; for a CrCl of 51 to 60 mL/min, reduce the dose by 30%; for a CrCl of 10 to 50 mL/min, reduce the dose by 50% to 80%; and for a CrCl less than 10 mL/min, avoid use[106] (Table 61-1).

### Pediatric Patients

MTX is commonly used in the pediatric population (see Table 61-1). It can be given orally or SQ, with a starting dose of 0.3 to 1 mg/kg/dose once weekly. It is common to start at 0.3 mg/kg/dose and escalate to a dose of 25 mg/wk. It is suggested that at doses greater than 15 mg/wk, parenteral application should be considered because of better bioavailability and tolerability. Guidelines for toxicity monitoring are similar to adult recommendations.

## Toxicity

Despite initial concerns, when given once a week in doses used for rheumatic diseases and monitored correctly, MTX is very well tolerated. Some of the toxicities of MTX (e.g., stomatitis, nausea, and bone marrow depression) are dose dependent, appear to be related to folate deficiency, and respond to folate replacement. Other toxicities (e.g., pneumonitis) appear to be idiosyncratic or allergic and, in most cases, require discontinuation of MTX. Still other toxicities, such as liver fibrosis and cirrhosis, appear to be multifactorial and may depend on the presence of concomitant risk factors, total dose, and frequency of administration.

### Gastrointestinal and Hepatic Side Effects

GI symptoms, including dyspepsia, nausea, and anorexia, are common, occurring in as many as 20% to 70% of patients

**TABLE 61-1** Special Considerations for DMARD Therapy

| | Fertility | Pregnancy | Lactation | Elderly | Pediatrics |
|---|---|---|---|---|---|
| Methotrexate | W: no effect<br>M: reversible sterility<br>Stop 3 mo before conception | Contraindicated<br>FDA category X; abortifacient; teratogenic | Contraindicated; present in breast milk | Lower initial dose (5-7.5 mg/wk); dose based on CrCl | Dosing based on weight |
| Leflunomide | No effect; test levels before conception; may require washout | Contraindicated<br>FDA category X; embryolethal; teratogenic | Contraindicated; unknown concentrations in breast milk | No dosage adjustment required | Dosing based on weight |
| Sulfasalazine | W: no effect<br>M: reversible sterility | Relatively safe;<br>FDA category B, C | Relatively safe; present in breast milk | No dosage adjustment required | Dosing based on weight |
| Hydroxychloroquine | No effect | Relatively safe;<br>FDA category C | Relatively safe; present in breast milk | No dosage adjustment required | Dosing based on weight |

CrCl, Creatinine clearance; FDA, U.S. Food and Drug Administration; M, men; W, women.

within the first year of therapy.[107] These symptoms may be attenuated by adding folic acid or by changing to a parenteral dosing regimen.

The risk of significant liver toxicity appears to be low when MTX is given once weekly to patients who abstain from alcohol and are monitored carefully, and occurs in approximately one patient per 1000 after 5 years of use.[108] However, a recent review of a large North American database of patients with RA and PsA found that elevations in aspartate aminotransferase (AST)/alanine aminotransferase (ALT) greater than 1 times the upper limit of normal (ULN) occurred in 22% and 31% of patients taking MTX or MTX and leflunomide, respectively. Elevations greater than 2 times ULN occurred in 1% to 2% on monotherapy and in greater than 5% on combination therapy. Elevated liver function tests (LFTs) were more likely in patients with PsA.[109] Alcohol consumption, $\alpha_1$–anti-trypsin deficiency, morbid obesity, diabetes, concomitant hepatotoxic drugs, and chronic hepatitis B or C have all been implicated as possible risk factors for MTX toxicity.[110]

### Hematologic Side Effects

Bone marrow toxicity, in most cases, is dose dependent and responds to folic acid administration. Pancytopenia, leukopenia, anemia, and thrombocytopenia can occur, but are rare. In a review by Gutierrez-Urena and associates, clinically significant pancytopenia was found to develop in as many as 1% to 2% of RA patients on MTX therapy.[111] Severe, life-threatening bone marrow toxicity can be treated with folinic acid (leucovorin) and, if necessary, granulocyte-stimulating factor (GSF). Because the elimination of MTX is dependent on the kidney, decreases in renal function may precipitate bone marrow toxicity in patients who have been previously stable. Additional risk factors include hypoalbuminemia, dosing errors, and concomitant use of probenecid or trimethoprim/sulfamethoxazole (TMP/SMX).

### Pulmonary Side Effects

Five clinical pulmonary syndromes have been associated with MTX treatment: acute interstitial pneumonitis (hypersensitivity pneumonitis), interstitial fibrosis, noncardiogenic pulmonary edema (seen in high-dose treatment for malignancy with rare reports in RA), pleuritis and pleural effusions, and pulmonary nodules.[112] Time lapse from initiation of therapy to cumulative dose before the onset of pulmonary toxicity is extremely variable, at 1 to 480 weeks and 7.5 to 3600 mg of MTX, respectively.[112] MTX-induced pulmonary disease is rare and is difficult to quantify, but estimates suggest an incidence of 3.9 cases per 100 patient-years of MTX exposure and a prevalence of 2.1% to 5.5%.[113,114] A recent meta-analysis of MTX and lung disease in RA has shown a modest increased risk of all respiratory events (relative risk [RR], 1.10; 95% confidence interval [CI], 1.02 to 1.19) and respiratory infection (RR, 1.11; 95% CI, 1.02 to 1.21), but not an increased risk for death from lung disease (RR, 1.53; 95% CI, 0.46 to 5.01) or noninfectious respiratory events (RR, 1.02; 95% CI, 0.65 to 1.60), when compared with other DMARDs and biologic agents.[115]

Patients generally are seen with shortness of breath, tachypnea, dry cough, and fever. Chest radiographs most typically show a bilateral interstitial infiltrate (although this finding varies). Infectious causes, including opportunistic organisms, must always be ruled out. If routine evaluations for infection, including sputum studies, and for other medical conditions to explain the pulmonary symptoms are negative, bronchoscopy with bronchoalveolar lavage and transbronchial biopsy is recommended. If MTX pulmonary toxicity is suspected, MTX should be discontinued and supportive treatment initiated with the use of corticosteroids in more severe cases. Some patients with pulmonary toxicity have been successfully restarted on MTX,[116] but clinicians have reported mortality in up to 50% of re-treated patients.[57]

Factors that appear to predispose to MTX lung toxicity include age, blue collar occupation, smoking (in women), diabetes, pleuropulmonary rheumatoid disease, and skin rashes from MTX.[117]

### Mucocutaneous Side Effects

The mucocutaneous toxicities of MTX, which have been reported to occur in up to one-third of patients, are dose dependent and respond to folate replacement. Patients generally report fairly minor oral ulcerations, but severe ulceration of the mouth, esophagus, bowel, and vagina can occur, especially at higher doses.

### Malignancies

The induction of malignancies by MTX is a concern, and several studies have examined this question with conflicting conclusions. Recently, reports of lymphoma in MTX-treated patients with RA have appeared. Because the incidence of lymphoma is already increased in patients with RA,[118] these reports are difficult to interpret. The case for a causative role of MTX has been strengthened, however, because a number of these cases have been B cell lymphomas of the type commonly seen in association with immunosuppression (associated with Epstein-Barr virus) and that may regress after discontinuation of MTX.[119,120] Subsequently, lack of a causal relationship between MTX treatment and the development of lymphoma has been seen in two large series of RA patients—one prospective study[118] and one retrospective study.[121] The potential benefits of MTX for most RA patients thus far outweigh these statistically small risks.[122]

### Miscellaneous

**Methotrexate Flu.** Patients taking MTX may describe flulike symptoms shortly after taking their weekly dose. Nausea, low-grade fevers, myalgias, and chills are the most common signs of the so-called *MTX flu*. These side effects usually respond to supplementation with folic acid, decreasing the dose, switching from oral to parenteral administration, or changing the time of the dose (so that the patient takes MTX right before going to bed).

**Nodulosis.** The development of, or increase in, the number or size of rheumatoid nodules has been reported to occur in patients with RA treated with MTX, with a prevalence of as much as 8%.[123] This may occur in rheumatoid factor–negative patients, and in those in whom the synovitis is under excellent control. The mechanism of this nodule formation has been suggested to be the result of an increase in adenosine, which appears to promote nodule formation.[124] Conversely, nodules have been reported to decrease during MTX therapy.

**Vasculitis.** Despite efficacy in the treatment of the cutaneous vasculitis associated with RA, leukocytoclastic vasculitis has also been attributed to MTX therapy.[125]

### Fertility, Pregnancy, and Lactation

MTX does not seem to adversely affect female fertility but can cause reversible sterility in men.[126] Women and men should discontinue MTX for at least 3 months before attempting to conceive because of its large distribution and long half-life in the liver. Folic acid supplementation is essential before conception. MTX is included in the FDA Pregnancy Category X and is contraindicated during pregnancy. Women of childbearing age who are considered for MTX therapy should receive extensive counseling regarding teratogenic risk and should be placed and maintained on adequate contraception, before therapy is begun. Toxicities include fetal abnormalities such as "aminopterin syndrome" (multiple craniofacial, limb, and CNS abnormalities)[127] and embryonic or fetal loss, and MTX at high doses (1 mg/kg) is an effective abortifacient. MTX is also contraindicated during lactation because small amounts are excreted in breast milk (see Table 61-1).

### Toxicity Monitoring

The American College of Rheumatology (ACR) has recently revised recommendations for the use of DMARDs, and these serve as an excellent resource.[128] Toxicities that require monitoring include myelosuppression, hepatotoxicity, and pulmonary toxicity. Baseline evaluation should include a complete blood count (CBC) with platelets, hepatitis B and C serology in high-risk patients, liver transaminases, and creatinine. Although these guidelines make no recommendations on the need for a baseline chest radiograph, this is a reasonable approach. Liver biopsies are not routinely recommended before MTX is initiated. The rare patients whom one wants to treat with MTX despite abnormalities in screening laboratory or other significant risk factors may require liver biopsy before MTX is initiated. In addition, biopsies are recommended only in those patients who continue to have enzyme abnormalities and for whom continuation of MTX therapy is contemplated.

Monitoring for toxicity should be done every 2 to 12 weeks and is based on the duration of therapy, with more frequent monitoring provided earlier in the course of treatment. Systems review and physical examination should include monitoring for symptoms or signs of myelosuppression (fever, infection, bruising, and bleeding), pulmonary toxicity (shortness of breath, cough, rales), GI intolerance (nausea, vomiting, diarrhea), and lymphadenopathy. Laboratory parameters that should be followed include a CBC with platelets, liver transaminases, and creatinine (Table 61-2).

It is important to consider vaccination status in any patient who is going to use MTX. RA patients have an increased incidence of death from pneumonia,[129] and MTX may reduce the immune response to pneumococcal antigen.[130] Thus any patient in whom MTX is going to be used should first receive the pneumococcal vaccination, with booster as appropriate. Vaccinations for hepatitis B virus for at-risk patients and yearly influenza vaccines are recommended as well. Caution should be exercised when administering live virus vaccinations to patients on MTX.

## Drug Interactions and Contraindications

### Drug Interactions

Drugs that are known hepatotoxins, such as SSZ, leflunomide, and azathioprine, may potentiate liver toxicity when used in combination. Organic acids such as sulfonamides, salicylates, NSAIDs, penicillin G, piperacillin, and probenecid competitively inhibit tubular secretion, and this delays MTX clearance.[131] MTX also undergoes distal tubular reabsorption, which may be enhanced by the addition of hydroxychloroquine (HCQ)[132] and blocked by the addition of folic acid.[131] Drugs that affect renal function should be used with caution because of the renal clearance of MTX and, therefore, the increased risk of MTX toxicity that could occur because of decreased clearance.

**TABLE 61-2** Safety Monitoring

| | Baseline | <3 Months of Drug Therapy | Monitoring Interval 3-6 Months of Drug Therapy | >6 Months of Drug Therapy | Contraindications |
|---|---|---|---|---|---|
| MTX | CBC, LFT, Cr, HBV, HCV; vaccinate: influenza, *Pneumococcus*, HBV | Every 2-4 wk | Every 8-12 wk | Every 8-12 wk | Active infection, symptomatic pulmonary disease, WBC <3000/mm$^3$, Plt <50,000/mL$^3$, CrCl <30 mL/min, history of myelodysplasia or recent lymphoproliferative disorder, LFT >2 × ULN, acute or chronic HBV or HCV, pregnancy, lactation |
| Leflunomide | CBC, LFT, Cr, HBV, HCV; vaccinate: influenza, *Pneumococcus*, HBV | Every 2-4 wk | Every 8-12 wk | Every 8-12 wk | Active infection WBC <3000/mm$^3$, Plt <50,000/mL$^3$, history of myelodysplasia or recent lymphoproliferative disorder, LFT >2 × ULN, acute or chronic HBV or HCV, pregnancy, lactation |
| Sulfasalazine | CBC, LFT, Cr; vaccinate: influenza, *Pneumococcus* | Every 2-4 wk | Every 8-12 wk | Every 8-12 wk | Sulfa allergy, Plt <50,000/mL$^3$, LFT >2 × ULN, acute HBV/HCV, some classes of chronic HBV/HCV |
| Hydroxychloroquine | CBC, LFT, Cr; complete ophthalmologic examination within 1 year | None | None | None | History of vision changes attributed to 4-aminoquinolone derivatives, some classes of untreated HBV/HCV |

*Monitoring at <3, 3-6, and >6 mo need only include CBC, LFT, and Cr.

CBC, Complete blood count; Cr, creatinine; CrCl, creatinine clearance; HBV, hepatitis B; HCV, hepatitis C; LFT, liver function test; Plt, platelets; ULN, upper limit of normal; WBC, white blood cell count.

From Saag K, Geng G, Patkar N: American College of Rheumatology 2008 recommendations for the use of nonbiologic and biologic disease-modifying anti-rheumatic drugs in rheumatoid arthritis. *Arthritis Rheum* 59:762–784, 2008.

Several of the aforementioned drugs deserve special mention. TMP-SMX should be avoided or used with extreme caution because of possible hematologic toxicity with MTX. Mechanisms for this toxicity include an additive anti-folate effect from TMP, decreased MTX clearance because of inhibition of tubular secretion by SMX, and altered MTX plasma protein binding. NSAIDs are commonly used in patients with RA as adjunctive therapy. NSAIDs may increase MTX levels by displacing MTX from plasma proteins and limiting tubular secretion. Despite lack of a significant pharmacokinetic or clinical interaction between low-dose MTX and a variety of NSAIDs,[133] vigilance for MTX toxicity should increase whenever NSAID dosages are changed in patients on stable weekly doses of MTX. Low doses of aspirin used for cardiovascular prophylaxis are not likely to be of concern. Furthermore, probenecid should be avoided because it inhibits tubular secretion of MTX.

### Contraindications

MTX should not be used in patients with severe renal, pulmonary, or hepatic impairment, pre-existing bone marrow suppression, alcoholic liver disease, and pregnancy or breastfeeding. Ongoing or active infection is also a contraindication. In most cases, patients who desire to continue drinking alcohol should not be treated with MTX. Mild to moderate renal insufficiency is a relative contraindication, and use of MTX in these patients may require more vigilant toxicity monitoring (Table 61-3).

## LEFLUNOMIDE

**KEY POINTS**

- **Leflunomide reversibly inhibits dihydroorotate dehydrogenase.**
- **Loading doses often are not used in clinical practice because of gastrointestinal toxicity.**
- **Because of enterohepatic recirculation, leflunomide has a very long half-life.**
- **Leflunomide is absolutely contraindicated in pregnancy, and levels must be checked with a washout protocol if needed before conception.**
- **Vigilance must be used for hepatotoxicity.**

Leflunomide, an isoxazole derivative, is a synthetic DMARD approved for the treatment of RA. It emerged from a specific anti-inflammatory drug development program and has potent immunomodulatory effects.

### Chemical Structure

Leflunomide is a low-molecular-weight isoxazole compound and is chemically unrelated to any previous immunosuppressant. Leflunomide is a pro-drug and is rapidly and completely converted to its active metabolite, the malononitriloamide A77 1726. A77 1726 is also known as *teriflunomide* (Figure 61-4).

**TABLE 61-3** Methotrexate, Leflunomide, Sulfasalazine, and Anti-malarials: Summary of Mechanism of Action, Efficacy, and Toxicity

| | Proposed Mechanism of Action | Efficacy | Toxicity |
|---|---|---|---|

Ag, Antigen; APS, anti-phospholipid syndrome; ATIC, 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase; DHFR, dihydrofolate reductase; DHODH, dihydroorotate dehydrogenase; JIA, juvenile idiopathic arthritis; LGL, large granular lymphocyte; MALT, mucosa-associated lymphoid tissue; MTX, methotrexate; PsA, psoriatic arthritis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TYMS, thymidylate synthetase; ↑, increased; ↓, decreased; →, indicates the result.

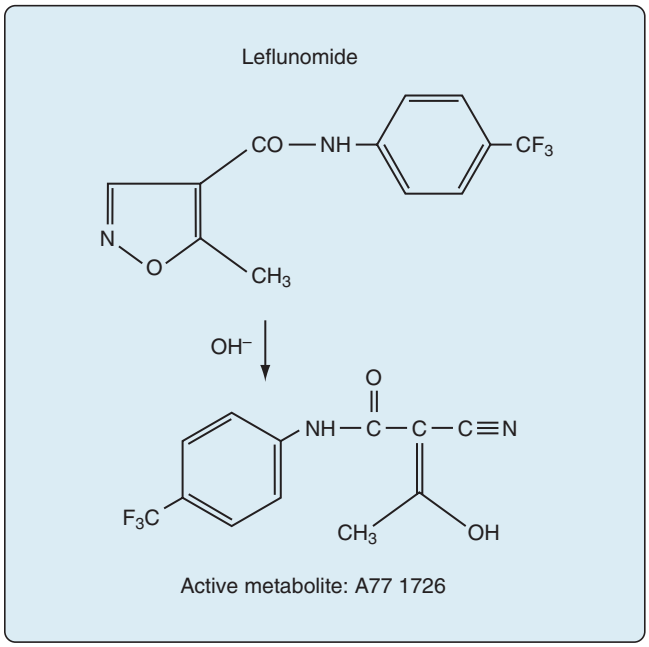

**Figure 61-4** Leflunomide is rapidly and completely metabolized to its active metabolite, A77 1726.

## Actions of Leflunomide

As with MTX, the precise mechanism of action responsible for the effects of leflunomide in rheumatic disease is not completely understood.[134] Leflunomide is immunomodulatory, with the net effect being a reduction in activated T lymphocytes. Its two in vitro mechanisms of action vary depending on concentration: (1) At the concentration of the active metabolite (A77 1726) achieved in patients, its major effect appears to be reversible inhibition of the enzyme dihydroorotate dehydrogenase (DHODH), which results in inhibition of pyrimidine synthesis; (2) at higher concentrations, A77 1726 also inhibits tyrosine kinases, interfering with cell signal transduction.[135]

Activation of T cells results in progression from the resting phase ($G_0$) to the $G_1$ phase, where ribonucleotides are synthesized, and then to the S phase, where cellular DNA is replicated in preparation for mitosis. T cell activation requires significant increases in de novo pyrimidine and purine biosynthesis. Sensors such as proto-oncogenes *(p53)* and checkpoints (cyclins C and D) in this pathway monitor the level of nucleotide pools and prevent damaged cells from replicating.[135]

Ribonucleotide uridine monophosphate (rUMP) is a precursor for the formation of pyrimidine nucleotides and thus is essential for both RNA and DNA synthesis. The steps in de novo rUMP synthesis are seen in Figure 61-5. A critical step in this pathway is the generation of dihydro-orotate in the cytoplasm with subsequent diffusion into the mitochondria, where the enzyme DHODH is located. DHODH converts dihydro-orotate to orotate, and the latter diffuses back into the cytoplasm and is subsequently converted to rUMP and, ultimately, to RNA and DNA.

The first postulated mechanism of action of leflunomide consists of inhibition of DHODH by A77 1726, which lowers orotate levels and leads to a decrease in rUMP and subsequent nucleotide synthesis, resulting in T cell cycle arrest. This mechanism of action has been substantiated by experimental evidence. In vitro mitogen-stimulated activation of T cells is blocked by levels of A77 1726 that inhibit DHODH, and this inhibition can be reversed by the addition of uridine, suggesting that A77 1726 works by disruption of pyrimidine biosynthesis.[136,137] Further, the only

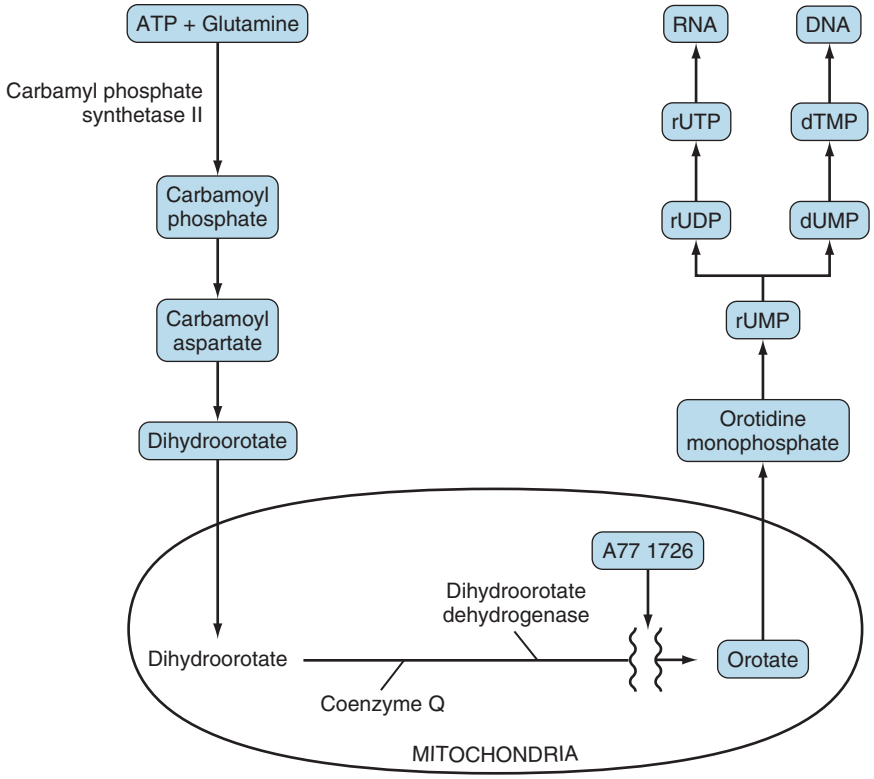

**Figure 61-5** The active metabolite of leflunomide, A77 1726, blocks the conversion of dihydroorotate to orotate within the mitochondria. ATP, Adenosine triphosphate; dTMP, 2-deoxythymidylate; dUMP, 2-deoxyuridylate; rUDP, ribonucleotide diphosphate; rUMP, ribonucleotide uridine monophosphate; rUTP, ribonucleotide triphosphate.

enzyme inhibited by A77 1726 in this pathway, at concentration obtained in vivo, is DHODH.[138]

Evidence also exists to support that inhibition of DHODH produces an arrest of lymphocytes in the $G_1$ phase of the cell cycle.[139] If the level of ribonucleotides, including rUMP, falls below a critical point, cytoplasmic p53 activation occurs, and p53 will translocate to the nucleus and initiate cellular arrest by ultimately preventing transcription of cyclins D and E. In cultures of human T cells, A77 1726 depletes rUMP pools and results in an accumulation of nuclear p53 with resultant cell cycle arrest.[140] In comparison, treatment of cell lines lacking p53 with A77 1726 does not cause a $G_1$ phase arrest.[141]

Resting lymphocytes maintain ribonucleotide requirements largely through salvage pathways and are essentially unaffected by leflunomide.[142] Active, or autoimmune, lymphocytes rely on the de novo pathway and are affected by leflunomide. During the course of treatment with this slow-acting agent, autoimmune lymphocytes should be removed progressively.[135]

At higher concentrations, A77 1726 inhibits phosphorylation of tyrosine kinases that are critical for cell growth and differentiation of activated cells.[143,144] This inhibition has been proposed to partially or completely explain the antiproliferative effects of leflunomide; however, it is unclear whether concentrations sufficient to achieve this effect are obtained in vivo.

Several other additional anti-inflammatory properties of leflunomide have been noted. Leflunomide has the ability to block the activation of nuclear factor-κB (NF-κB),[145] which regulates the expression of genes important in inflammatory processes, including those seen in inflammatory arthritis.[146] Ex vivo and in vitro studies in humans have shown that both leflunomide and MTX inhibit neutrophil chemotaxis, which may decrease the recruitment of inflammatory cells into the joints.[44] Leflunomide also decreases the ratio of MMP-1 to TIMP-1.[44] Finally, leflunomide alters the synthesis of cytokines by augmenting the immunosuppressive cytokine-transforming growth factor-β1 and suppressing the immunostimulatory cytokine IL-2.[147]

## Pharmacology

### Absorption and Bioavailability

The GI tract and the liver rapidly and completely convert ingested leflunomide into A77 1726. Food does not interfere with absorption. Circulating A77 1726 is highly bound (>99%) to plasma proteins, predominantly albumin. Its plasma concentration is linearly correlated with a single oral dose over a range of 5 to 25 mg; steady state is reached in 7 weeks after daily dosing.[148]

### Distribution and Half-Life

A77 1726 has a half-life of approximately 2 weeks (mean, 15.5 days),[148] with a low apparent volume of distribution. A77 1726 undergoes enterohepatic recirculation. In healthy individuals, 90% of leflunomide is excreted by 28 days,[148] but some may be present for much longer periods.

### Elimination

In healthy individuals, the proportions excreted by the kidney and the gut are nearly equal. Because detectable A77 1726 may be present in the body months or years later, the ability to rapidly and effectively eliminate A77 1726 with cholestyramine is important. Oral administration of cholestyramine, 8 g three times daily for 11 days, can lower the apparent half-life of A77 1726 to 1 to 2 days.[149] Furthermore, activated charcoal, 50 g every 6 hours, can reduce plasma levels by 50% within 24 hours.[149]

### Indications

**Rheumatoid Arthritis.** Leflunomide was first shown to be safe and effective in treating RA in a placebo-controlled, dose-ranging, 6-month trial.[148] Two pivotal trials, one in Europe and one in the United States, have compared leflunomide with SSZ and MTX. The European trial had three treatment arms: leflunomide (20 mg/day after a loading dose), SSZ (increased to 2 g/day), and placebo.[150] In this trial, both leflunomide and SSZ were superior to placebo in terms of swollen and tender joint counts, as well as physicians' and patients' overall assessments. It is important to note that both the leflunomide and SSZ groups reported significant effects on slowing of radiographic progression of disease compared with placebo. The U.S. trial compared patients treated with leflunomide (20 mg/day after a loading dose), MTX (7.5 to 15 mg/wk), or placebo.[151] Again, both active drugs were found to be superior to placebo but not different from each other. Both leflunomide and MTX also slowed radiographic progression of disease compared with the placebo group. Another trial compared leflunomide (20 mg/day with loading) with MTX (10 to 15 mg/wk) in a 1-year trial with a 1-year extension.[152] In this trial, MTX was shown to be statistically superior to leflunomide for the clinical outcomes measured, as well as the rate of radiographic progression after 2 years.

**Other Rheumatic Diseases.** Leflunomide has been reported to be effective in treating systemic lupus erythematosus. In a randomized, controlled trial, leflunomide was more effective than placebo in improving markers of lupus disease activity, and was safe and well tolerated.[153] A subsequent small, prospective, open-label trial of patients with lupus nephritis unresponsive to conventional therapy showed that leflunomide was efficacious and well tolerated.[154]

Leflunomide has been shown to be effective in treating PsA and psoriasis when compared with placebo.[155] In an open-label trial of AS, leflunomide was shown to be effective in treating peripheral arthritis, but axial symptoms did not improve.[156]

Both an open-label trial[157] and a randomized, controlled clinical trial[158] have shown the efficacy of leflunomide in maintaining remission in granulomatosis with polyangiitis after successful induction with cyclophosphamide. In the latter trial, leflunomide was superior to MTX in preventing relapse.

Leflunomide is also safe and effective in patients with juvenile idiopathic arthritis (JIA) who did not respond to or could not tolerate MTX.[159]

## Dose and Drug Administration

Leflunomide is available in oral tablets at doses of 10, 20, and 100 mg. Oral leflunomide is rapidly metabolized to A77 1726, which has a very long half-life; therefore the standard recommendation is to start therapy with a loading dose of 100 mg daily for 3 days, then switch to the standard maintenance dose of 20 mg daily. Despite this recommendation, many clinicians no longer prescribe a loading dose because it is believed to increase the drug's GI toxicity.[160] Also, it is common practice to decrease the dose to 10 mg daily if toxicity occurs, or if complete control of the disease can be maintained. Because of its long half-life, some clinicians give leflunomide less often (three to five times per week).

### Geriatric Patients

No pharmacokinetic studies specific to geriatric patients have been done for leflunomide; hence dosing recommendations are the same as for the general population. No clinical experience in patients with renal insufficiency has been reported, so those patients should be monitored carefully. See Table 61-1.

### Pediatric Patients

Although not approved in the United States to treat patients with JIA, leflunomide is used off-label for this condition at a dose of 10 to 20 mg/day. This dosing is often based on a patient's body weight. A recently published example of dosing by body weight is as follows: A patient weighing less than 20 kg receives 10 mg every other day, a patient weighing more than 20 kg but less than 40 kg receives 10 mg/day, and a patient weighing more than 40 kg receives 20 mg/day.[161] See Table 61-1.

## Toxicity

For major controlled trials that have used leflunomide at a dose of 20 mg/day, the incidence of adverse events that resulted in trial withdrawal are shown in Table 61-4. Leflunomide-associated withdrawals (19%) were more frequent than those associated with MTX (14%), were similar in frequency to those associated with SSZ (19%), but were more frequent than those associated with placebo treatment (8%).

### Gastrointestinal and Hepatic Side Effects

The most common side effect that limits the use of leflunomide is diarrhea, which responds to dose reduction and may

**TABLE 61-4** Leflunomide Trial Withdrawals for Adverse Events

| | No. of Patients | Withdrawals |
|---|---|---|
| Leflunomide | 816 | 154 (19%) |
| Methotrexate | 680 | 94 (14%) |
| Sulfasalazine | 133 | 25 (19%) |
| Placebo | 210 | 16 (8%) |

be less common if the loading dose is not used. Abdominal pain, dyspepsia, and nausea from leflunomide appear to be slightly increased versus placebo rates.

Liver toxicity can occur in association with leflunomide administration. Data from a large U.S. cohort of RA and PsA patients show that elevations in ALT/AST levels greater than 1 × ULN occurred in 17% and elevations greater than 2 × ULN occurred in 1% to 2% of patients taking leflunomide. Leflunomide given in combination with MTX resulted in ALT/AST elevations greater than 1 × ULN in 31% and greater than 2 × ULN in 5% of patients. Furthermore, this change in transaminases was more commonly seen in patients with PsA.[109] The European Agency for Evaluation of Medicinal Products (EMEA) reported 296 patients with hepatic abnormalities and 15 patients with liver failure and death while taking leflunomide.[162,163] The FDA reviewed adverse event reports between August 2002 and May 2009, and found 49 cases of severe liver injury, 14 of which resulted in death.[164] Most patients with hepatotoxicity have risk factors, including concomitant administration of another hepatotoxic agent or underlying liver disease.

### Cardiovascular Side Effects

Hypertension has consistently been reported to occur more frequently in leflunomide-treated compared with placebo-treated patients.[150,151] Additionally, elevation of cholesterol levels has been reported in association with leflunomide use.[165] Both of these effects should be monitored because of the excess cardiovascular mortality reported in patients with RA.

### Miscellaneous

**Dermatologic.** Skin rashes have been reported, most commonly occurring between the second and fifth months of treatment and necessitating discontinuation of the drug. Severe skin reactions such as Stevens-Johnson syndrome or toxic epidermal necrolysis require leflunomide washout with cholestryramine.

An increased incidence of alopecia has been reported in clinical trials in association with leflunomide treatment.

**Pulmonary.** Recent reports have suggested that leflunomide can cause interstitial lung disease (ILD), usually within 3 months of starting therapy. Patients with preexisting ILD are at highest risk for this potentially fatal complication.[166,167]

**Hematologic.** Rare cases of pancytopenia have been reported in post-marketing surveillance, primarily in patients with known risk factors for blood dyscrasias. An increased risk of lymphoproliferative disorders has not been associated with leflunomide.

**Weight Loss.** Significant weight loss has also been reported to occur in patients taking leflunomide.[168]

### Fertility, Pregnancy, and Lactation

Leflunomide is rated Pregnancy Category X. Animal studies have demonstrated substantial teratogenic and embryolethal effects with small doses of leflunomide. Therefore women of childbearing potential should be strongly counseled about this, and leflunomide should not be prescribed for women who are not practicing reliable birth control methods. A pregnancy test should be considered before therapy is initiated. Leflunomide excretion in milk is unknown; therefore nursing mothers should not receive leflunomide.

It is critically important to note that the active metabolite of leflunomide (A77 1726), largely because of its enterohepatic circulation, may remain in the body for years. Therefore, if a woman who has previously received leflunomide wishes to become pregnant, A77 1726 levels should be measured. Active elimination of leflunomide from the body should be considered for levels above 0.02 mg/L. This can be achieved by the oral administration of cholestyramine for 11 days (8 g, three times daily).[169] Before pregnancy is attempted, verification of levels below 0.02 mg/L should be confirmed on two separate occasions, at least 14 days apart, and the woman should then wait an additional three full menstrual cycles.[170] Patients may require more than one course of cholestyramine to achieve this level. Although no data exist, men wishing to father children should undergo the same washout procedure as women and should wait an additional 3 months after the second drug plasma level is verified to be below 0.02 mg/L (see Table 61-1).

### Toxicity Monitoring

Similar to MTX, the ACR has published guidelines on the initiation and monitoring of leflunomide treatment.[128] Patients taking leflunomide should have a baseline CBC and liver enzyme monitoring, including AST, ALT, and albumin. Serum creatinine measurement is important because leflunomide is partially eliminated by the kidney. The frequency of monitoring depends on the duration of therapy (see Table 61-2). More frequent monitoring may be warranted if concomitant immunosuppressive agents, such as MTX, are given. If patients experience significant toxicity, a washout procedure is indicated to more rapidly eliminate the drug. Caution should be exercised when live virus vaccinations are administered to patients on leflunomide.

## Drug Interactions and Contraindications

### Drug Interactions

Cholestyramine interferes with enterohepatic recycling of leflunomide, resulting in lower serum concentrations. Concomitant use with hepatotoxic agents, including MTX, increases the risk of liver toxicity, and leflunomide must be used with caution and monitored judiciously. Rifampin may increase the serum concentration of A77 1726. Leflunomide may potentiate warfarin therapy.

### Contraindications

Leflunomide should not be used in patients with impaired liver function, severe renal impairment, bone marrow dysplasia, severe immunodeficiency, severe hypoproteinemia, or known hypersensitivity to the drug. The liver is involved in enterohepatic recirculation and biliary excretion; thus

leflunomide use in liver disease is contraindicated. In renal insufficiency, the levels of circulating A77 1726 do not appear to be increased, but the component of free A77 1726 is increased. Leflunomide is contraindicated in the setting of serious infection and should be discontinued in patients with new or worsening pulmonary symptoms or rash. Leflunomide is absolutely contraindicated in pregnancy and breastfeeding (see Table 61-1).

## SULFASALAZINE

**KEY POINTS**

- **Sulfasalazine (SSZ) has anti-microbial and anti-inflammatory properties, but the exact mechanism of action is unknown.**
- **SSZ is commonly used as part of combination therapy for RA.**
- **Gastrointestinal intolerance is a common side effect.**
- **Although rare, surveillance for leukopenia is important early in the course of the treatment.**

SSZ was the first agent to be synthesized specifically for rheumatoid arthritis in 1938, by Professor Nanna Svartz of Stockholm, in collaboration with the Swedish pharmaceutical company Pharmacia. The prevailing notion at that time was that RA was caused by infection, and SSZ was designed with both anti-inflammatory and anti-bacterial properties.

### Chemical Structure

Salicylazosulfapyridine (SASP), now known as *sulfasalazine*, is a conjugate of the anti-inflammatory 5-aminosalicylic acid (5-ASA or *mesalamine*) and the anti-bacterial sulfapyridine joined by an azo bond (Figure 61-6). The abbreviation SASP is still in use as an alternative to SSZ.

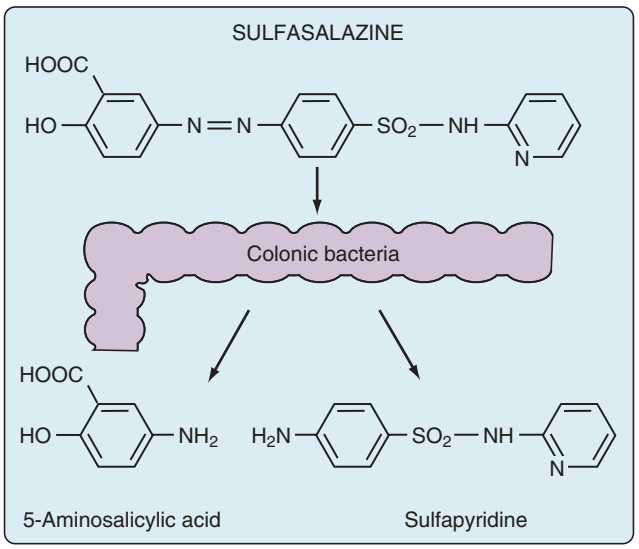

**Figure 61-6** Sulfasalazine and its major metabolites.

### Actions of Sulfasalazine

Despite more than 7 decades of use, the mechanism of action of SSZ in rheumatic disease still is not fully elucidated. When SSZ was designed, its anti-microbial properties were thought to be fundamentally important in the successful treatment of RA, which was postulated to be an enteropathic arthropathy. Through alteration of gut flora, SSZ may downregulate the immune response leading to inflammatory arthritis. Although this hypothesis has never been disproved, this mechanism of action has fallen out of favor for several reasons. To date, no conclusive evidence has been found for an infectious cause of RA, other sulfonamides have failed to result in clinical improvement, and a relationship between gut flora and clinical response to SSZ is lacking.[171] Currently, SSZ is presumed to work via anti-inflammatory and immunomodulatory effects.

SSZ has been demonstrated in vitro to possess multiple anti-inflammatory properties. First, SSZ weakly inhibits the pro-inflammatory effects of the arachidonic acid cascade, with a slight inhibitory effect on prostaglandin $E_2$ synthetase activity,[172] as well as lipoxygenase products.[173] SSZ also downregulates neutrophil chemotaxis, migration, and proteolytic enzyme production and degranulation,[174,175] and inhibits neutrophil activation by decreasing the flux of second messengers involved in intra-cellular signal transduction.[176] Neutrophil migration to sites of inflammation can be downregulated by adenosine. SSZ inhibits folate-dependent enzymes, including AICAR transformylase (ATIC) and DHFR, resulting in increased adenosine release into the extra-cellular milieu.[177] Gadangi and colleagues confirmed that SSZ, similar to MTX, modulates inflammation via increased adenosine release.[178] This effect appears to be the result solely of SSZ because sulfapyradine and 5-ASA are inactive. SSZ is a more potent inhibitor of ATIC than MTX.

SSZ also possesses multiple immunomodulatory properties. In vitro, SSZ inhibits T cell proliferation, natural killer cell activity, and B cell activation, with resultant declines in immunoglobulin synthesis and RF production.[171] In all of these systems, sulfapyridine and 5-ASA are less active than SSZ. Cytokine profiles are also altered by SSZ, resulting in inhibition of the T cell cytokines IL-2[179] and IFN-γ,[180] and the monocyte/macrophage cytokines IL-1, TNF, and IL-6.[181,182] NF-κB is a key transcription factor that when active mediates the transcription of key cytokines, adhesion molecules, and chemokines essential to mounting an immune response. In vitro, SSZ, but not sulfapyridine or 5-ASA, inhibits NF-κB translocation to the nucleus.[183]

SSZ, more so than sulfapyridine, inhibits endothelial cell proliferation and angiogenesis, which likely contributes to the synovitis of RA.[184] The synovial fibroblast also plays a key role in the pathogenesis of RA, and SSZ inhibits fibroblast proliferation and metalloproteinase synthesis.[185] Finally, SSZ inhibits the formation of osteoclasts and may be anti-resorptive in RA.[186]

The active moiety of SSZ is controversial. The parent compound, SSZ, appears to have the most biologic activity when compared with sulfapyridine and 5-ASA. However, the SSZ levels needed in vitro to see the anti-inflammatory and immunomodulatory effects are far greater than those obtained in vivo. No demonstrable relationship has been

shown between plasma SSZ, sulfapyridine, and 5-ASA levels that correlate with clinical efficacy, so serum levels may be irrelevant.[171] In an open, nonrandomized study comparing two groups of patients who received either sulfapyridine or 5-ASA in doses that would represent the molar equivalent of 2 g of SSZ, the group receiving sulfapyridine showed significant improvement in erythrocyte sedimentation rate (ESR) and in some clinical parameters, including grip strength and joint circumference.[187] Taken together, it would appear that both SSZ and sulfapyridine have a role in therapeutic efficacy for RA.

One potential site of action for SSZ that may explain its systemic action despite low serum levels is the mucosa-associated lymphoid tissue (MALT) in the small bowel.[171] In the gut lumen, the therapeutic concentration of SSZ is at least two times greater than in the serum, and drug concentration in the surrounding mucosal tissue is likely also high. The gut immune system is extensive, and active communication with the rest of the body occurs via migration and recirculation of activated lymphocytes.[171] Furthermore, a link between MALT and the joints has been suggested.[188] Evidence that some of the efficacy of SSZ may be mediated via MALT is described as follows. Treatment with SSZ decreases circulating immunoglobulin (Ig)A-producing cells and serum levels of IgA, correlating with disease improvement[189]; SSZ reduces gut mucosa lymphocytes in treated patients[190]; and SSZ has been shown to modulate an immune response elicited by an oral antigen in mice and healthy volunteers.[191]

## Pharmacology

### Absorption and Bioavailability

Less than 30% of SSZ is absorbed by the small bowel; most undergoes enterohepatic circulation and is secreted unchanged in the bile, with a resulting bioavailability of 10%.[171] The steady-state serum concentration of SSZ is 5 μg/mL after an oral dose of 2 g/day. Most SSZ reaches the colon, where intestinal bacteria reduce the azo bond and release the two active components: sulfapyridine and 5-ASA.[192] Most of the sulfapyridine is absorbed from the colon (>90%) and appears in plasma 4 to 6 hours after an oral dose (steady-state serum concentration of 30 μg/mL after 2 g/day dose). Most of the 5-ASA (80% to 90%) remains in the bowel.[171] Sulfapyridine and SSZ are likely the active components in rheumatic disease, and 5-ASA is the active component in ulcerative colitis.[193]

The bioavailability of standard SSZ is similar to that of enteric-coated SSZ.[194] Administration of SSZ with food decreases the blood concentration of both SSZ and sulfapyridine.[195]

### Distribution and Half-Life

Both SSZ and sulfapyridine are widely distributed in the body with more than 99% and 50% to 70% plasma protein binding, respectively.[171,195] Serum and synovial concentrations are comparable.[196] The half-life of SSZ is 6 to 17 hours, with upper-range values characteristic of older patients, and the half-life of sulfapyridine is 8 to 21 hours, with upper-range values characteristic of slow acetylators.[197]

### Elimination

Sulfapyridine is extensively metabolized in the liver by *N*-acetylation and ring hydroxylation with subsequent glucuronidations,[198] and because of genetic variations in acetylator phenotype, wide variability is seen among individuals.[197] Slow acetylators have a reduced clearance rate and higher serum sulfapyridine concentrations. Sulfapyridine is excreted in the urine, and 5-ASA is eliminated primarily in the feces. The small portion of 5-ASA that is absorbed is excreted in the urine as *N*-acetylmesalamine.[199]

### Indications

**Rheumatoid Arthritis.** Multiple published trials since the early 1980s have showed significant benefit in both clinical and laboratory parameters for SSZ (2 to 3 g daily) versus placebo in the treatment of RA.[200] A meta-analysis of randomized controlled clinical trials of SSZ for the treatment of RA was published in 1999.[201] In this analysis, SSZ was compared with placebo and other single DMARD therapies, including HCQ, D-penicillamine (D-Pen), and gold sodium thiomalate or aurothioglucose. In trials of SSZ versus placebo, SSZ was shown to be superior to placebo in patient improvement in multiple clinical parameters. The withdrawal rate because of lack of efficacy was significantly greater in the placebo group than in the SSZ group; however, more patients in the SSZ group than in the placebo group withdrew because of adverse effects ($P$ <0.0001). No single DMARD emerged as clinically superior in this meta-analysis. Subsequent studies have demonstrated equivalent clinical efficacy with SSZ and MTX,[202,203] as well as with SSZ and leflunomide,[150] although a 2-year extension trial did show that beneficial effects are sustained to a greater extent with leflunomide than with SSZ.[204]

**Spondyloarthropathies**

Psoriatic Arthritis. A recently published systematic review of therapies for psoriatic arthritis looked at six randomized controlled trials comparing SSZ with placebo in PsA.[205] Results show that SSZ is efficacious in treating the peripheral arthritis of PsA, but does not appear to influence the axial manifestations.[206] Few data on the prevention of radiographic progression are available.

Ankylosing Spondylitis. A recent meta-analysis reviewed 11 trials that included 895 patients with AS treated with SSZ or placebo.[207] In all patients with AS, SSZ showed some benefit in reducing ESR and easing spinal stiffness. The authors concluded that SSZ may benefit patients at an early disease stage with a higher ESR and peripheral arthritis. This finding is in agreement with those of Clegg and co-workers, who found a significant benefit for SSZ in peripheral arthritis, but not in axial arthritis, in patients with AS.[206]

Reactive Arthritis. Most cases of ReA resolve spontaneously; others become chronic with peripheral or axial arthritis. In a randomized, controlled trial of 134 male veterans with ReA (predominantly peripheral arthritis) who were unresponsive to NSAIDs, SSZ was more effective than placebo.[208]

Inflammatory Bowel–Associated Arthritis. SSZ has been used effectively to treat ulcerative colitis and distal Crohn's disease. No randomized controlled trials have investigated SSZ in terms of peripheral or axial arthritis manifestations

of these diseases, although SSZ is used in clinical practice for peripheral arthritis.

**Juvenile Inflammatory Arthritis.** SSZ is effective in polyarticular and pauciarticular juvenile inflammatory arthritis. A literature review by Brooks in 2001 found reports of 550 patients with juvenile inflammatory arthritis (half with polyarticular and one-third with pauciarticular disease) treated with SSZ.[209] Results showed at least some drug-associated benefit in all subtypes, with the best response noted in late-onset pauciarticular disease and the least benefit observed in systemic-onset disease. Toxicity and intolerance were similar to those noted with adult use of SSZ, except for a substantial incidence of serum sickness in patients with systemic-onset disease.

## Dosing

SSZ is available in regular and enteric-coated tablets of 500 mg and in a suspension of 50 mg/mL. To minimize side effects, most clinicians will prescribe 500 mg daily and will escalate the dose by 500 mg/day every week to the standard dose of 1500 to 3000 mg, divided daily. Dose reduction may ameliorate side effects. Because SSZ can inhibit enzymes in the folate-dependent pathway, concomitant administration of folic acid may be beneficial.

### Geriatric Patients

Dosing recommendations for SSZ in geriatric patients are the same as for the general adult population.[106] Studies of pharmacokinetics in the elderly have shown that although the elimination half-life is longer, it is primarily dependent on acetylator phenotype; however, the dose should be reduced for renal insufficiency.[104] See Table 61-1.

### Pediatric Patients

In pediatric patients, SSZ is dosed initially at 10 to 12.5 mg/kg/day, with a weekly dose increase of 50 mg/kg/day in two divided doses, until a maintenance dose of 2 g/day is achieved. This can be increased to 3 g/day if no response is seen with lower doses. See Table 61-1.

## Toxicity

In general, a majority of adverse effects from SSZ occur within the first several months of treatment and decrease with continued use.[210] The most common early adverse effects include GI effects, headache, dizziness, and rash. They tend to decrease with continued use.[195]

### Gastrointestinal and Hepatic

Nausea and upper abdominal discomfort are the most common adverse effects with SSZ. Nausea frequently occurs with CNS effects, including dizziness and headache. In one large cohort of 1382 RA patients, GI/CNS effects were reported as transient in 8% of patients; SSZ was continued and in another 18% led to discontinuation of therapy.[211] Nausea is more common in patients who achieve higher sulfapyridine levels and in slow acetylators.[212] Diarrhea can occur, usually in the first several months. GI effects may be decreased by administration of enteric-coated preparations. Elevations in liver transaminases may occur and are usually transient. However, they may be accompanied by fever, rash, hepatomegaly and, possibly, eosinophilia.[210]

### Hematologic

Hematologic disturbances are rare, occurring in less than 3% of patients; they usually occur within the first 3 months.[195] The most common abnormalities include leukopenia that usually reverses upon cessation of the drug, although some cases of fatal agranulocytosis have been reported, warranting continued surveillance.[213] Macrocytosis and hemolysis have been reported with SSZ; its use should be avoided in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Folic acid supplementation may be reasonable because of SSZ effects on folate metabolism. Thrombocytopenia is rare.

### Dermatologic

Rashes occur in less than 5% of patients, usually in the first 3 months of therapy.[211] Rashes are usually maculopapular, pruritic, and generalized, although urticaria develops in some patients. Desensitization to SSZ has been reported.[214] Anecdotally, erythema multiforme, toxic epidermal necrolysis, and Stevens-Johnson syndrome have been rarely reported, but were not seen in the major clinical trials. Photosensitivity has also been reported. Patients in whom a rash develops while on SSZ should be cautioned to avoid other sulfonamide-containing agents, such as thiazide diuretics, celecoxib, and antibiotics.

### Pulmonary

Pulmonary toxicity from SSZ is rare and manifests as reversible infiltrates with peripheral eosinophilia, cough, dyspnea, fever, and weight loss.[215] Pathology reveals an eosinophilic pneumonia with interstitial infiltrates with or without fibrosis. Most cases resolve with discontinuation of SSZ with or without corticosteroids.

### Miscellaneous

Minor reactions, such as irritability, anxiety, headache, and difficulty sleeping, may occur.[210,211] Rare cases of drug-induced lupus,[216] hypogammaglobulinemia,[216] and aseptic meningitis have been reported.[217] Advise patients that they may experience orange discoloration of their urine, sweat, and tears.

### Fertility, Pregnancy, and Lactation

No reports have described diminished fertility in women taking SSZ; however, men can have oligospermia, impaired sperm motility, and abnormal sperm morphology[218] that returns to normal 2 to 3 months after cessation of the drug. SSZ is considered FDA Category B, C for pregnancy. SSZ and sulfapyridine cross the placenta, and fetal concentrations are equivalent to maternal concentrations; however, SSZ does not seem to cause or increase fetal abnormalities or spontaneous abortions, and may be one of the DMARDs

of first choice for treating rheumatic disease in women of childbearing age who are or wish to become pregnant.[126] Sulfapyridine is excreted into breast milk, and one report described a child in whom bloody diarrhea developed, which led the American Academy of Pediatrics to classify SSZ as a drug that must be given with caution to nursing women[126] (see Table 61-1).

### Toxicity Monitoring

Most side effects from SSZ occur early in the course of treatment. The ACR guidelines recommend a baseline CBC with platelets, liver enzyme monitoring (including AST, ALT, and albumin), creatinine, and consideration for G6PD.[128] The frequency of monitoring depends on the duration of therapy (see Table 61-2). Vaccination with *Pneumococcus* should be given if appropriate at the initiation of therapy, and yearly influenza vaccination is recommended (see Table 61-2).

## Drug Interactions and Contraindications

### Drug Interactions

Few SSZ-drug interactions are known. SSZ may impair absorption of digoxin and decrease its bioavailability. Rarely, SSZ can increase the effects of oral hypoglycemics and the anti-coagulant effects of warfarin. Broad-spectrum antibiotics may alter gut flora and decrease the bioavailability of sulfapyridine and 5-ASA through reduced cleavage of the azo bond.

### Contraindications

Patients with hypersensitivity to any component of SSZ, or with a sulfonamide or salicylate allergy, should not be prescribed SSZ. Caution should be used in patients with porphyria or GI or genitourinary obstruction. SSZ should not be used in thrombocytopenia, severe liver disease, and active viral hepatitis (see Table 61-2).

# ANTI-MALARIALS

**KEY POINTS**

- **Hydroxychloroquine (HCQ) is a well-tolerated DMARD that is commonly used in combination therapy regimens for RA.**
- **HCQ is more commonly used than chloroquine.**
- **HCQ has a very long half-life, attributed to its affinity for melanin-containing cells in the skin.**
- **Doses of HCQ should not exceed 6.5 mg/kg in chronic therapy to minimize the risk of retinal toxicity.**
- **Although routine laboratory monitoring is not required, ophthalmologic screening is an essential component of toxicity monitoring.**
- **Diabetic patients initiating HCQ should be instructed to follow blood sugars closely because of the hypoglycemic effects of the drug.**
- **HCQ is considered safe in pregnancy; it is recommended that most pregnant patients with SLE remain on the drug to improve pregnancy outcomes.**

The aminoquinolones, including quinine, were first derived from the bark of the Peruvian cinchona tree, and were originally used to treat malaria. To reduce toxicity, the 4-aminoquinolines, chloroquine (CQ), and HCQ were developed. CQ and HCQ are the most common anti-malarials prescribed, although quinacrine is used occasionally.

## Chemical Structure

HCQ and CQ are very similar in their chemical structure, differing only by the substitution of a hydroxyethyl group for an ethyl group on the tertiary amino nitrogen of the side chain of CQ. Quinacrine includes the CQ structure, although it is not a 4-aminoquinolone derivative (Figure 61-7).

## Actions of Hydroxychloroquine

Anti-malarial agents have both immunomodulatory and anti-inflammatory properties, although their precise mechanism of action in rheumatic disease is unknown. Because HCQ and CQ are weak bases, they can pass through cytoplasmic membranes into cytoplasmic vesicles and accumulate, thereby increasing the vesicle pH from approximately

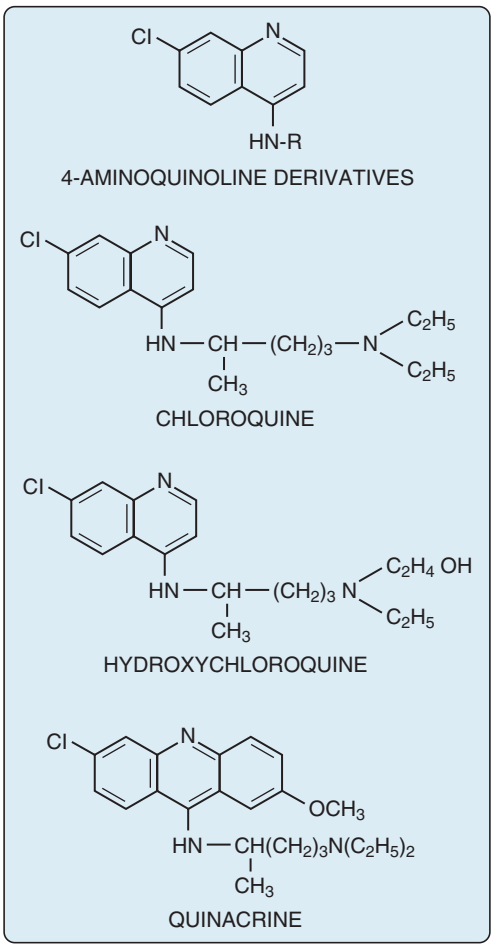

**Figure 61-7** Chemical structures of anti-malarial drugs used to treat rheumatic disease and the basic structure of 4-aminoquinolones. *R* represents the side chain.

4.0 to 6.0 and interfering with acid-dependent subcellular functions. This increased pH has several postulated immunoregulatory effects, including stabilization of lysosomal membranes, attenuation of antigen processing and presentation, and inhibition of cell-mediated cytotoxicity.[219,220] Macrophages and monocytes require precise pH concentrations for protein digestion and antigen processing, which is altered with an increased pH.[221] Furthermore, receptor assembly is disrupted, including the class II major histocompatibility complex (MHC) molecules, because a higher pH in the endoplasmic reticulum stabilizes the MHC protein with invariant chains and prevents their displacement by low-affinity autoantigens. This, combined with decreased membrane receptor recycling, leads to downregulation of antigen presentation.[219,221,222] Furthermore, anti-malarial treatment decreases circulating immune complexes.[223]

Anti-malarials also have inhibitory effects on pro-inflammatory cytokines. CQ inhibits IL-1 and IFN-γ production by monocytes and T cells.[224] CQ also inhibits macrophage TNF mRNA transcription and endotoxin-induced secretion of TNF, IL-1, and IL-6.[225] Studies of HCQ have yielded conflicting results in terms of the ability to inhibit TNF, but HCQ blocks IL-1, IL-6, and IFN-γ production by monocytes.[226,227]

Apoptosis or cell death plays an important role in regulation of the immune system, and defects in apoptosis may allow for longevity and persistence of autoreactive lymphocyte clones and perpetuation of autoimmunity. Both CQ and HCQ upregulate apoptosis and may downregulate autoimmunity by elimination of autoreactive lymphocytes.[220] Furthermore, anti-malarials inhibit the proliferative response of human lymphocytes and natural killer cell activity.[228,229]

Anti-inflammatory properties of the anti-malarials include effects on the arachidonic acid cascade caused by downregulation of phospholipases $A_2$ and C, which contribute to the production of pro-inflammatory prostaglandins and lipid peroxidation.[230-232] Lipid peroxidation is thought to play a role in apoptosis, particularly in response to ultraviolet (UV)A and UVB irradiation.[233] Anti-malarial agents also have antioxidant properties and may protect against tissue damage from free radicals.[234]

Anti-malarials have several other beneficial effects relevant to rheumatic disease that warrant further discussion. First, they are photoprotective, and this is likely the result of locally induced anti-inflammatory effects.[220] Second, both HCQ and CQ inhibit platelet adhesion and aggregation, leading to an anti-thrombotic effect.[235,236] Third, HCQ and CQ favorably alter the lipid profile, with reductions in total cholesterol, triglycerides, very-low-density lipoproteins (VLDLs), and low-density lipoproteins (LDLs), particularly in patients on concomitant corticosteroid therapy.[220,237] Finally, HCQ and CQ have been reported to decrease plasma glucose levels through inhibition of insulin degradation in the Golgi apparatus.[220,238]

## Pharmacology

### Absorption and Bioavailability

HCQ and CQ are administered orally and are rapidly and completely absorbed, with the peak plasma concentration for both occurring within 8 hours.[239] Considerable variability in blood concentrations has been reported among patients treated with the same dose, but higher plasma levels do not correlate with a better therapeutic response.[220]

### Distribution and Half-Life

Anti-malarials accrue in different concentrations in various tissue compartments. Relatively small concentrations, similar to those seen in the plasma, are contained in fat, bone, tendon, and brain. Increased concentrations are seen in the kidney, bone marrow, spleen, lungs, adrenal glands, and liver. The highest concentration occurs in melanin-containing cells, such as those in the skin and the retina.[240] In fact, the skin can serve as a long-term reservoir whereby the drug can exert its effect, or toxicity, even after it has been stopped.[220] The half-life of HCQ and CQ is 40 to 50 days, and plasma levels will increase gradually and equilibrate after 3 to 4 months.[241]

### Elimination

Most of the absorbed drug is excreted in the urine unchanged, but some is metabolized to a desethyl derivative. The remainder is excreted in the feces.[242]

### Indications

**Rheumatoid Arthritis.** The efficacy of anti-malarial agents in rheumatoid arthritis has been seen in their ability to control signs and symptoms of the disease[243-245]; however, they do not retard bone erosions.[246] In a meta-analysis of anti-malarials, HCQ was found to be less toxic but also less effective than CQ.[247] In comparison with other DMARDs, symptomatic efficacy is equal to or slightly less than that of other agents, and they have the slowest onset of action.[248] Anti-malarial agents are particularly suited for use in early, mild RA and in combination therapy.

**Systemic Lupus Erythematosus.** Although anti-malarials are not appropriate as monotherapy for severe manifestations of SLE, they are used frequently to control constitutional symptoms, arthritis, fever, fatigue, and rash. The most convincing data supporting the efficacy of anti-malarials in SLE come from studies in which the medication was discontinued in successfully treated patients. In one double-blind, placebo-controlled drug discontinuation study of 47 SLE patients in remission on HCQ, the risk of disease flare was increased by a factor of 2.5 in the placebo group.[249] Anti-malarials are particularly suited to treat SLE because of their photoprotective effects, and they are especially useful in dermatologic manifestations of SLE.

**Discoid Lupus.** Anti-malarials are effective in discoid lesions, with remission or major improvement reported in 60% to 90% of treated patients.[229] When HCQ or CQ treatment alone is unsuccessful, the addition of quinacrine may be helpful, but long-term use may be limited by the development of yellowish skin pigmentation.[250]

**Anti-phospholipid Antibody Syndrome.** HCQ use is associated with a decreased incidence of thrombosis in patients with anti-phospholipid (aPL) antibodies.[251] HCQ

also diminishes thrombus size and time in mice injected with aPL antibodies, and to reverse aPL antibody–mediated platelet activation.[252,253] Although clinical trials are needed to further establish efficacy, it is reasonable to consider the use of HCQ in patients with aPL antibody syndrome, especially if they are unable to tolerate high levels of anti-coagulation, or if they develop thrombosis despite oral anti-coagulation.[254]

**Sjögren's Syndrome.** HCQ improves local eye and mouth symptoms, arthralgia, and myalgia in a prospective open-label study of patients with Sjögren's syndrome.[255] In addition to causing the immunomodulatory and anti-inflammatory effects discussed earlier, HCQ may inhibit glandular cholinesterase activity and enhance salivary gland secretion.[256]

**Miscellaneous.** Anti-malarials have been reported to be efficacious in small and uncontrolled trials for the treatment of palindromic rheumatism,[257] childhood systemic lupus erythematosus,[258] childhood dermatomyositis,[259] eosinophilic fasciitis,[260] and erosive osteoarthritis.[261] In a controlled trial of 17 patients, the arthritis of calcium pyrophosphate crystal deposition disease improved more in the HCQ than in the placebo group.[262]

## Dosing

HCQ comes in 200 mg tablets, CQ is available in 250 mg and 500 mg tablets, and quinacrine is available from compounding pharmacies. To prevent ocular toxicity, dosing should be adjusted for weight. HCQ should be maintained at a dose of 6.5 mg/kg or less for ideal body weight, or 5.0 mg/kg or less for actual body weight, and the dose of CQ should be 3 mg/kg or less.[263,264] Ideal body weight can be calculated using a simplified formula: for women, 100 lb for the first 5 feet of height, plus 5 lb for every inch of height over 5 ft (45 kg for the first 1.5 m of height, plus 2.3 kg for each 2.5 cm of height over 1.5 m); for men, 110 lb for the first 5 feet of height, plus 5 lb for every inch of height over 5 feet (50 kg for the first 1.5 m of height, plus 2.3 kg for each 2.5 cm of height over 1.5 m).[265] In practice, doses of HCQ rarely exceed 400 mg daily, in divided doses, and doses of CQ rarely exceed 250, dosed daily; HCQ and CQ are both cleared by the kidney and the liver. Diseases of either organ may lead to increased serum drug levels. To reduce the risk of retinal toxicity, dose adjustment is needed for a glomerular flow rate less than 60 mL/min (stage 3 or higher chronic kidney disease).[264]

### Geriatric Patients

No specific pharmacokinetic studies have explored the use of anti-malarials in the elderly; thus dosing recommendations are the same as for the general population.[106] Elderly patients should be screened at baseline for pre-existing ocular disease. See Table 61-1.

### Pediatric Patients

HCQ is used at a dose of 3 to 5 mg/kg/day, typically to a maximum of 400 mg/day. To achieve this dosing in younger children and use the 200 mg tablets, the drug can be dosed every other day. Alternatively, HCQ can be compounded in a 25 mg/mL suspension. It is generally recommended that ophthalmologic screening occur every 6 months; however, some suggest that screening every 12 months is sufficient. See Table 61-1.

## Toxicity

### Ophthalmologic

Early eye symptoms can include defects in accommodation or conversion or blurred vision, which resolves. Retinal toxicity is the most feared side effect. A recent retrospective case-control study found the prevlence of retinal toxicity to be 7.5% with the following risk factors: dosage level too high for weight (OR, 5.67; 95% CI, 4.14 to 7.7 for >5.0 mg/kg actual body weight); duration of use (OR, 3.22; 95% CI, 2.20 to 4.70 for >10 years); kidney disease (OR, 2.08; 95% CI, 1.44 to 3.01 for stage 3 or higher chronic kidney disease); and concurrent tamoxifen use (OR, 4.59; 95% CI, 2.05 to 10.27).[264] CQ has a higher risk of retinal toxicity than HCQ.[266] Within 10 years of use, the prevalence of retinal toxicity remained low (<2%) but rose to nearly 20% after 20 years of use.[264]

HCQ or CQ retinopathy is described as bilateral bull's eye maculopathy, with retinal pigment epithelial (RPE) cell depigmentation in the central macula and sparing of a small foveal island. Testing of the paracentral visual field can usually show toxicity before RPE changes are visible. When advanced, visual loss may be irreversible and may continue despite cessation of the drug because of its long half-life in the retina; so early detection is essential. CQ and HCQ can also cause corneal deposits, which can be associated with halos around lights and are benign and reversible.

### Dermatologic

Rash is a common side effect leading to discontinuation of therapy. HCQ may also cause photosensitivity, alopecia, and depigmentation of hair.[247]

### Neuromuscular

Common neuromuscular symptoms include headache, insomnia, nightmares, and irritability, which are mild and reversible with lowering of the daily dose. Tinnitus and deafness can occur. Neuromyotoxicity has been reported and presents as proximal weakness of insidious onset with a normal creatine phosphokinase (CPK), which may be associated with peripheral neuropathy and cardiac myotoxicity. Muscle biopsy shows curvilinear bodies and muscle fiber atrophy with vacuolar changes.[267]

### Cardiovascular

Rarely, conduction disturbances and cardiomyopathy have been reported.[268]

### Gastrointestinal

Anorexia, nausea, vomiting, diarrhea, and abdominal cramping have been reported.[247]

### Metabolic

HCQ can reduce blood glucose levels and hemoglobin $A_{1C}$, so diabetic patients need to be cautioned to watch their blood sugars closely with initiation of HCQ and may need adjustments in their diabetic medications.[269]

### Fertility, Pregnancy, and Lactation

No reports have described adverse effects on fertility. HCQ and CQ are considered FDA Pregnancy Category C.[126] Because of the long half-life of HCQ, discontinuation of the drug at the time of pregnancy does not avoid fetal exposure. HCQ does cross the placenta, but there have been no reports of adverse outcomes or teratogenic effects in women who continue HCQ during pregnancy.[126] CQ also crosses the placenta and binds more tightly in tissue than HCQ; fetal anomalies in women who took CQ during pregnancy have been reported.[270] Quinacrine should not be used in pregnancy because it is mutagenic. Current recommendations are that HCQ may be continued throughout pregnancy, particularly in SLE, where discontinuation could precipitate a flare, which would be dangerous to both mother and baby.[170] HCQ is also found in low concentration in breast milk, but the American Academy of Pediatrics classifies it as compatible with breastfeeding[126] (see Table 61-1).

### Toxicity Monitoring

The ACR recommends baseline screening with CBC, liver transaminases, and creatinine. Subsequently, no routine laboratory monitoring is recommended.[128] In 2002, the American Academy of Ophthalmology (AAO) released an information statement on screening recommendations for CQ and HCQ retinopathy.[263] Revised guidelines were published in 2011.[271] With new data showing the risk of retinal toxicity increasing toward 1% after 5 to 7 years of use, or a cumulative dose of 1000 g of HCQ, a baseline examination is advised to rule out underlying ocular pathology, including maculopathy, which may render subsequent toxicity screening more difficult to interpret. Annual eye examinations should commence at 5 years or sooner depending on other risk factors.[271] At a minimum, this should include a dilated eye examination, visual field testing with Humphrey 10-2 fields, and screening for color blindness in male patients. In addition, newer objective tests should be used that are more sensitive than visual fields (multifocal electroretinogram, spectral domain optical coherence tomography, and fundus autofluorescence). Despite these recommendations, many rheumatologists would favor annual screening or, at a minimum, screening every 2 years. Vaccination with a yearly influenza vaccine is recommended (see Table 61-2).

## Drug Interactions and Contraindications

### Drug Interactions

HCQ should be used with caution in diabetic patients on hypoglycemic agents. HCQ increases digoxin levels. CQ may increase cyclosporine levels and reduce MTX levels. CQ can interfere with cytochrome P450 enzymes and should be used with caution when combined with other agents metabolized by this pathway. Concomittant use with tamoxifen produces synergism for the risk of retinal toxicity.[264]

### Contraindications

Hypersensitivity to or previous retinal or visual field changes attributable to 4-aminoquinoline agents and severe liver disease caused by viral hepatitis are contraindications to further use (see Table 61-2).

# COMBINATION DMARD THERAPY IN RHEUMATOID ARTHRITIS

**KEY POINTS**

- Monotherapy with MTX infrequently induces remission in RA.
- Combinations of DMARDs can have superior efficacy without increased toxicity.
- MTX is the cornerstone of combination therapy.
- Combinations of traditional DMARDs are as effective as combinations of MTX plus biologic therapy
- Current research is focused on the best strategies for introduction, timing, and patient selection for combination therapy.

In the early 1990s, the use of combinations of DMARDs to treat RA was rare; now this strategy is used by essentially all rheumatologists to treat many of their patients.[272] Currently, the timing and make-up of combinations selected to treat RA is one of the most important decisions that clinicians face.

Monotherapy with MTX is considered by most as the initial treatment of choice for early RA. Four major studies have demonstrated the superiority of combinations of DMARDs versus monotherapy in head-to-head comparisons.[68,273-275] Trials with multiple conventional DMARDs and biologics have shown them to be more effective than placebo when added to the baseline MTX in patients who have active disease despite MTX therapy. With very few exceptions, successful combination trials have included MTX, and it remains the cornerstone of combination therapy.

## History of Combination DMARD Therapy

Early combination DMARD studies were initiated in the late 1970s. The combination of cyclophosphamide, azathioprine, and HCQ produced substantial responses in a small group of patients; however, an unacceptably high number of malignancies were reported.[276] Thus early enthusiasm for combination therapy was limited. During the 1980s, inadequate dosing, the use of DMARDs with marginal efficacy, and problematic trial design contributed to the less-than-exciting results reported with combination therapy. In 1994, the first trial to convincingly show superior efficacy without increased toxicity of combination DMARD therapy in a head-to-head comparison with mono-DMARD therapy was reported,[277] and multiple

trials showing the success of combination therapy have ensued.

## Early Rheumatoid Arthritis

In the late 1990s, three pivotal trials showed the success of combination DMARD therapy in early RA. Researchers in the Netherlands reported success with a step-down approach in the COBRA (Combinatietherapie Bij Reumatoide Artritis) trial.[273] In this trial, patients with early disease were randomly assigned to two groups. A combination of prednisolone, MTX, and SSZ was compared with SSZ alone. Prednisolone was started at 60 mg/day, rapidly tapered, and discontinued by week 28. MTX was given until week 40. The dose of SSZ was the same in the two groups. At 28 weeks, the combination group was significantly better than the SSZ-alone group. While prednisolone and MTX were tapered, clinical responses became similar in the two groups; however, significant benefits in certain parameters were noted in the combination group.[278] It is important to note that combination therapy was not more toxic. Subsequent data confirm that the radiographic benefits conferred by COBRA in the initial trial continued for at least 5 years.[278]

The second important early RA study is the Finland Rheumatoid Arthritis (Fin-RA) trial.[275] In this open trial, patients were randomly assigned to receive combination DMARD therapy (MTX, SSZ, HCQ, and low-dose prednisolone) or monotherapy with SSZ with optional prednisolone. The major endpoint of this trial was remission at 2 years. Significantly, patients who received combination therapy achieved more frequent remissions. A follow-up of this trial at 5 years demonstrated that patients treated initially with the combination were less likely to have evidence of C1-C2 subluxation on cervical spine radiographs.[279]

In a third trial from Turkey, patients with early RA were randomly assigned to receive single DMARD therapy (MTX, SSZ, or HCQ), two-drug therapy (MTX and SSZ or MTX and HCQ), or three-drug therapy (MTX, SSZ, and HCQ), with remission at 2 years as the major outcome.[274] For all endpoints measured, two drugs were statistically superior to monotherapy, and three drugs were statistically superior to the two-drug regimens.

The TEAR (Treatment of Early Aggressive RA) trial (see Chapter 71) enrolled patients with early RA and compared initial combination therapy with MTX, SSZ, and HCQ (triple) or MTX and etanercept with initial MTX monotherapy with step-up to combination therapy at 6 months for patients with a Disease Activity Score (DAS) 28-ESR of 3.2 or greater. Results show that either initial combination therapy is superior to MTX monotherapy at 6 months, with a reduction in DAS28-ESR for combined groups of 4.2 versus 3.6 ($P < 0.0001$). There were no differences in DAS28-ESR seen between either of the initial combination regimens. Between weeks 48 and 102, there were no significant differences in DAS28-ESR between combination groups, whether started as initial or step-up therapy. By week 102, there was a statistically significant change from the baseline modified Sharp/van der Heijde score between the group receiving initial MTX plus etanercept versus triple (0.64 vs. 1.69; $P = 0.047$).[280]

In sum, combination therapy, whether step-up or initial therapy, has been shown in multiple trials to be superior to MTX alone in early rheumatoid arthritis. Predictors of who may respond to MTX monotherapy alone and who needs early combination therapy are still lacking.

## Patients with Active Disease Despite Methotrexate

Combination DMARD therapy was first studied in groups of patients with active disease despite MTX therapy, or suboptimal MTX responders. The first study to show the advantage of combination therapy with MTX and another DMARD compared with continued therapy with MTX alone in this group of patients was the cyclosporine-MTX trial[281] (Figure 61-8). Therapy with the combination of MTX, SSZ, and HCQ, so-called triple therapy, is well tolerated[68,274,275,282] and more effective than MTX monotherapy[68,274,280] or SSZ monotherapy,[275] and, in an open trial of patients with early disease, more effective than the double combination of MTX and SSZ or MTX and HCQ.[274]

In 1996, a 2-year, randomized, double-blind, parallel study of 102 established patients with RA was done to compare triple-drug therapy (MTX, SSZ, and HCQ) versus double therapy (HCQ and SSZ) versus monotherapy with MTX.[68] Significantly more patients receiving triple-drug therapy achieved a modified Paulus 50% response,[283] compared with those given double therapy. Triple therapy was well tolerated, and numerically fewer withdrawals occurred in the combination group compared with the other two groups. This therapy is durable, with 62% of patients remaining on triple therapy for 5 years continuing to maintain a 50% efficacy response.[284]

In follow-up, a 2-year, double-blind trial on patients with moderately advanced disease was done in 2002, in which the triple combination group was compared with two double-combination groups (MTX plus SSZ and MTX plus HCQ) in a head-to-head comparison.[282] Patients were stratified for previous MTX use, and previous users had to have active disease despite receiving 17.5 mg/wk. The triple-therapy group and both double-therapy groups tolerated their treatments well, with only 8% withdrawing for toxicities, which were mostly minor. Triple therapy is superior to either of the double combinations.

A double-blind, placebo-controlled trial (see Figure 61-8) compared the addition of leflunomide or placebo to baseline MTX in suboptimal MTX responders.[285] Leflunomide or placebo was added to MTX. The combination group was statistically superior to the MTX-placebo group in terms of the American College of Rheumatology 20 (ACR20) set criteria for clinical response. The combination was reasonably well tolerated, but side effects including diarrhea, nausea, and dizziness were increased in the combination arm. Elevated ALT levels (>1.2 times normal) occurred more frequently in patients on combination therapy than in those on MTX alone, with increases leading to withdrawal in 2.3% of patients who received the combination. The Rheumatoid Arthritis: Comparison of Active Therapies (RACAT) trial, was a 48 week double-blind, noninferiority trial of 353 established patients with RA with active disease despite MTX therapy (see Chapter 71). Groups were randomly assigned to receive triple DMARD therapy (MTX,

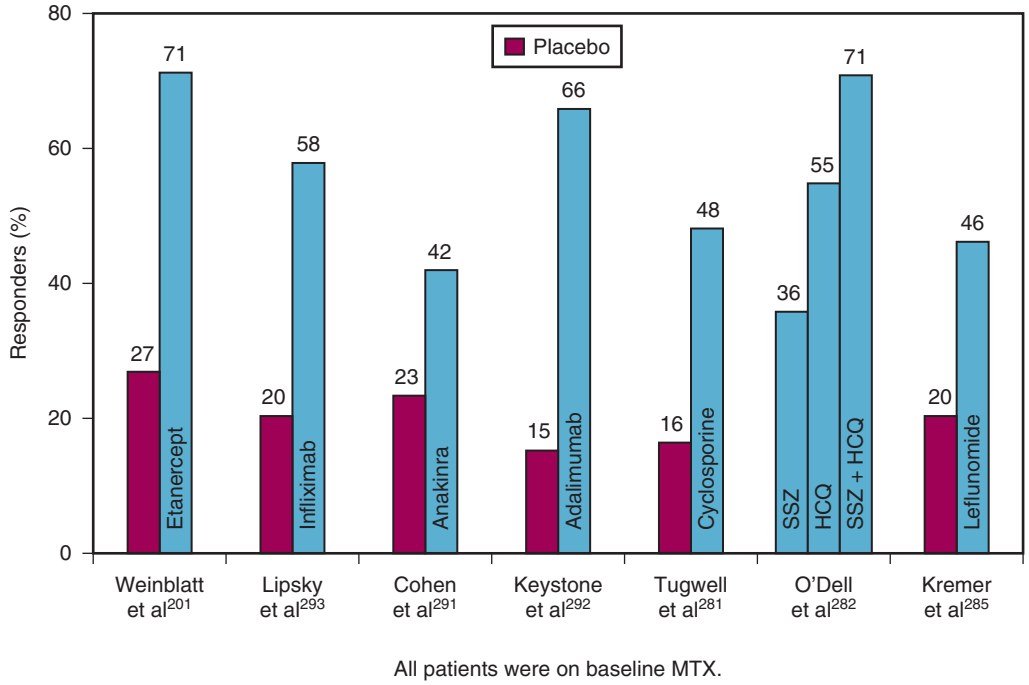

**Figure 61-8** Summary data taken from seven different clinical trials of therapies in patients with active disease despite methotrexate therapy. HCQ, Hydroxychloroquine; MTX, methotrexate; SSZ, sulfasalazine.

SSZ, HCQ) versus MTX and etanercept.[286] Patients who did not respond by week 24 were switched in a blinded fashion to the other therapy. The primary outcome was improvement in the DAS28. Both groups had significant improvement in the first 24 weeks, with only 27% in each group requiring a switch in therapy. Improvement was seen in both of the groups who switched therapy ($P$ <0.001) and the response after switching did not differ significantly between the two groups ($P$ = 0.08). The change in DAS28 (baseline to 48 weeks) was –2.1 with triple therapy and –2.3 with MTX plus etanercept. Triple therapy is noninferior to MTX plus etanercept ($P$ = 0.002). Cost-effectiveness analyses have revealed that the strategy of first using triple therapy before adding etanercept is cost-effective. In this analysis, the cost for one quality adjusted life-year is approximately $1 million (unpublished data).

## Corticosteroids in DMARD Combinations

Corticosteroids have not traditionally been considered DMARDs. However, they clearly fulfill all of the criteria for DMARDs, including halting radiographic progression.[287] Few clinicians who care for patients with RA dispute their efficacy. Indeed, they have been used as baseline therapy for more than half of the patients included in the combination trials discussed previously.

Prednisolone undoubtedly was a critical component for the success of the combination therapy for early rheumatoid arthritis (COBRA) protocol[273] and may have played a role in the success of the combination group in the Fin-RA trial.[275] Kirwan and colleagues' report of the ability of prednisolone to significantly retard radiographic progression of RA compared with placebo is testament to the efficacy of steroids when used in combination with other DMARDs.[287,288] Corticosteroids clearly deserve further formal investigation as a component of combination therapy. The COBRA trial and the Kirwan data have raised another interesting question: Should/could short courses of high-dose steroids be used as a form of induction therapy?[289]

## Biologic Agents in DMARD Combinations

Biologic agents that block TNF (etanercept, infliximab, adalimumab, certolizumab, and golimumab) and IL-1 (anakinra) have been studied in patients with early-stage and established RA in combination with MTX[290-298] (see Figure 61-8). These trials have shown superior improvements in clinical and radiographic endpoints in the combination groups.[295,296] Other biologic agents—rituximab, an anti-CD20 monoclonal antibody; abatacept, a T cell co-stimulatory inhibitor; tocilizumab, an IL-6 receptor antagonist; and tofacitinab, an oral Janus kinase inhibitor—have been studied in combination with MTX.[299-302] In the REFLEX (Randomized Evaluation of Long-Term Efficacy of Rituximab in RA) trial, rituximab versus placebo was added to baseline MTX in patients with RA who were suboptimal responders to MTX with failure of one or more TNF inhibitors.[299] Results showed that the combination group had significant improvements in ACR-N responses. Abatacept versus placebo in addition to background MTX was studied in patients with RA who had a suboptimal response to MTX, and results at 1 year showed significant improvements in clinical and radiographic endpoints.[300] The LITHE (Tocilizumab Safety and the Prevention of Structural Joint Damage) study compared the addition of tocilizumab versus placebo in MTX nonresponders and showed an improvement in structural outcomes at 1 year.[301] Concerns do exist regarding the risks of infection and

infusion reaction in combination therapy that includes biologic agents.

## Selecting the Right Patients for the Right Combination Therapy

Factors that predict a poor prognosis for patients with RA are well accepted and include rheumatoid factor, elevated ESR and CRP, the number of joints involved, erosions, and the presence of certain genetic markers. However, unless these factors can be shown to predict response to certain therapies in a differential fashion, they are of limited therapeutic use. Patient characteristics recommending one therapeutic regimen versus another remain to be fully elucidated. Genetic differences have been suggested to influence outcomes in a differential fashion. Until this observation can be corroborated and factors that predict response to other therapies elucidated, choices will remain largely empiric.

Treatment of patients with RA by using MTX combinations should be the gold standard against which future therapies are compared. Available data demonstrate that a variety of combinations are more effective than MTX alone. Until recently, no direct head-to-head trials comparing combinations of traditional DMARDs to MTX plus biologic agents existed. The TEAR and RACAT trials have shown that the use of traditional DMARD combinations (MTX, SSZ, HCQ) is as effective as combinations that include biologic agents (MTX plus etanercept) as initial therapy and, importantly, in MTX nonresponders. Recent guidelines published by the ACR[303] and the European League against Rheumatism (EULAR)[304] recommendations for the use of DMARDs and biologic agents in RA support this premise.

Although more information is available every day, many questions remain to be answered regarding the appropriate timing of combination therapy and the optimal combinations for specific patients and for specific clinical situations. Future research is needed to clarify the role of corticosteroids and, particularly, biologic response modifiers as components of and alternatives to MTX combination regimens.

CHAPTER 62

# Immunosuppressive Drugs

Jacob M. Van Laar

**KEY POINTS**

- Immunosuppressive drugs are effective and indispensable as remission-inducing and maintenance agents in the management of inflammatory rheumatic conditions. They constitute a heterogeneous group of compounds, each with a unique mode of action and toxicity profile.
- The long-term use of immunosuppressive drugs is associated with an increased risk of bacterial, viral, and fungal infection, as well as a reduced response to vaccinations.
- Cyclophosphamide is a commonly used drug for remission induction in persons with severe systemic lupus erythematosus (SLE) and necrotizing vasculitis. Its toxicities include myelosuppression, infection, ovarian failure, hemorrhagic cystitis, and malignancy, including bladder cancer, especially with high cumulative doses.
- Azathioprine can be effective as a glucocorticoid-sparing agent in remission maintenance therapy, particularly in persons with SLE and necrotizing vasculitis. It can induce severe myelosuppression in patients with low or absent thiopurine methyltransferase (TPMT) activity, which is affected by a polymorphism that can be identified by genetic screening. Severe myelosuppression also can occur in patients with normal TPMT activity, and regular monitoring of white blood counts is recommended.
- The interaction of azathioprine and allopurinol can lead to fatal myelosuppression and should be avoided.
- Cyclosporine can be effective in refractory rheumatoid arthritis, psoriatic arthritis, SLE, and inflammatory eye disease. It affects renal function and blood pressure, and dose reduction may be necessary. Drug interactions between cyclosporine and other drugs can result in clinically relevant changes in plasma concentrations of cyclosporine and/or concomitant medication.
- Mycophenolate mofetil can be used as a remission induction agent in persons with lupus nephritis and is now commonly used for remission maintenance treatment of SLE and necrotizing vasculitis. It is generally well tolerated, although diarrhea and leukopenia may necessitate its discontinuation.
- Tacrolimus is used only rarely for rheumatologic indications, usually in the event that conventional therapies fail.
- Cytostatic agents should be avoided in pregnancy and lactation, and referral to a fertility clinic should be considered for all fertile male and female patients. Other immunosuppressive drugs should only be used during pregnancy if the potential benefits outweigh the potential risks.

Immunosuppressive drugs comprise different classes of drugs that dampen the immune system—notably T and B lymphocytes—functionally and/or numerically (Table 62-1) but do not permanently correct the fundamental imbalance of immune regulation in autoimmune disease. As such, they do not have curative potential, yet they can be effective in remission induction and control of specific rheumatic disease manifestations, and they remain cornerstone drugs in the management of rheumatic conditions. Many immunosuppressive drugs have withstood the test of time, as attested by their ongoing use in transplantation medicine, nephrology, gastroenterology, ophthalmology, dermatology, and rheumatology. Consequently, their therapeutic potential and toxicity profiles hold few surprises. Apart from drug-specific toxicities, the main risk of immunosuppressive treatment is infection. In the absence of validated biomarkers of infection, sound clinical judgment and experience remain indispensable in monitoring patients who use immunosuppressive drugs, often for long periods. The use of live vaccines is contraindicated, and although other vaccinations are generally less effective, annual influenza vaccination is recommended in patients being treated with immunosuppressive medication. Pneumococcal vaccination also should be considered in select patients in accordance with (inter)national guidelines.

This chapter outlines the clinical pharmacology and therapeutic use of immunosuppressive drugs used in rheumatology. These drugs include cytostatic agents that affect bone marrow progenitor cells (cyclophosphamide and azathioprine) and drugs such as cyclosporine, tacrolimus, and mycophenolate mofetil (MMF) that target lymphocytes by inhibiting specific intra-cellular signaling pathways and/or proliferation. Their effects on the immune system overlap with those of traditional disease-modifying antirheumatic drugs such as methotrexate, glucocorticoids, and biologics. The most commonly used immunosuppressive drugs—cyclophosphamide, azathioprine, and MMF—are discussed in more detail. Glucocorticoids, traditional disease-modifying anti-rheumatic drugs (e.g., methotrexate, leflunomide, sulfasalazine, and hydroxychloroquine), biologics, and novel intra-cellular targeting agents are discussed elsewhere. The role of other immunosuppressive drugs (e.g., thalidomide, chlorambucil, sirolimus, and everolimus) in routine rheumatologic clinical practice has not been sufficiently established to merit discussion.

## CYCLOPHOSPHAMIDE

Cyclophosphamide was introduced as a cytotoxic agent in 1958 and is still one of the most potent immunosuppressant

drugs available. In combination with glucocorticoids, cyclophosphamide is particular effective as a remission induction agent in severe systemic lupus erythematosus (SLE) and necrotizing vasculitis.

## Structure

Cyclophosphamide is an oxazaphosphorine-substituted nitrogen mustard and inactive prodrug that requires enzymatic bioactivation (Figure 62-1). Cyclophosphamide belongs to the class of alkylating agents that substitute alkyl radicals into DNA, resulting in cell death. Cyclophosphamide is the alkylating agent of choice for most rheumatic disease requiring such therapy.

## Mechanisms of Action

The DNA-alkylating effects of cyclophosphamide are mediated predominantly through phosphoramide mustard and, to a lesser extent, other active metabolites. These positively charged, reactive intermediates alkylate nucleophilic bases, resulting in the cross-linking of DNA and of DNA proteins, breaks in DNA, and consequently decreased DNA synthesis and apoptosis.[1] The cytotoxicity of alkylating agents correlates with the amount of DNA cross-linking, but the relationship between cytotoxicity and immunosuppressive effects is unclear. The effects of cyclophosphamide are not exclusively limited to proliferating cells or particular cell types. Sensitivity varies among cell populations, however; for example, hematopoietic progenitor cells are relatively resistant to even high doses of cyclophosphamide. The immunosuppressive effects of cyclophosphamide include decreased numbers of T lymphocytes and B lymphocytes, decreased lymphocyte proliferation, decreased antibody production, and suppression of delayed hypersensitivity to new antigens with relative preservation of established delayed hypersensitivity.[2]

**TABLE 62-1** Mechanisms of Action of Immunosuppressive Drugs

| Drugs | Class | Mechanism of Action |
|---|---|---|
| Cyclophosphamide | Alkylating cytotoxics | Active metabolites alkylate deoxyribonucleic acid |
| Azathioprine | Purine analogue cytotoxics | Inhibit purine synthesis |
| Cyclosporine, tacrolimus (FK506) | Calcineurin inhibitors | Inhibit calcium-dependent T cell activation and interleukin-2 production |
| Mycophenolate mofetil | Purine synthesis inhibitor | Mycophenolic acid inhibits inosine monophosphate dehydrogenase |

## Pharmacology

### Absorption and Distribution

Oral and intravenous (IV) administration of cyclophosphamide results in similar plasma concentrations.[3] Peak plasma concentrations of cyclophosphamide occur 1 hour after oral administration. Protein binding of cyclophosphamide is low (20%), and it is widely distributed.[1]

### Metabolism and Elimination

Cyclophosphamide is rapidly metabolized, largely by the liver, to active and inactive metabolites. The formation of the active 4-hydroxycyclophosphamide is mediated by various cytochrome P450 (CYP) enzymes, and genetic variations in the enzymes in patients with lupus nephritis affect responses to cyclophosphamide.[4] 4-Hydroxycyclophosphamide, which is not cytotoxic at physiologic pH, readily diffuses into cells and spontaneously decomposes into the active phosphoramide mustard. The elimination half-life of cyclophosphamide is 5 to 9 hours, and alkylating activity is undetectable in the plasma of most patients 24 hours after a dose of 12 mg/kg.[1] Plasma concentrations of cyclophosphamide are not clinically useful predictors of either efficacy or toxicity. Between 30% and 60% of the total cyclophosphamide is eliminated in the urine, mostly as inactive metabolites, although some cyclophosphamide and active metabolites such as phosphoramide mustard and acrolein also can be detected in urine.[1]

### Pharmacokinetic Considerations in Special Circumstances

**Liver Disease.** Although the half-life of cyclophosphamide is increased to 12 hours in patients with liver failure

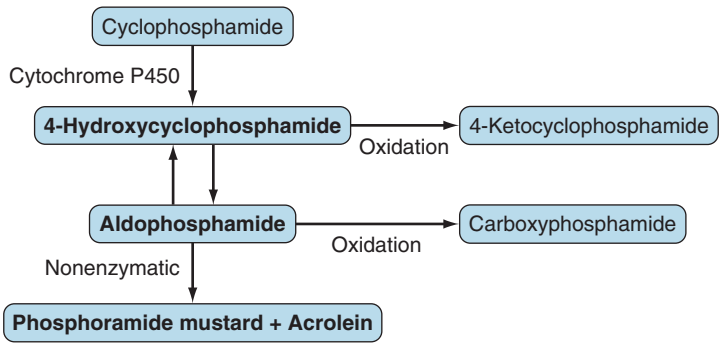

**Figure 62-1** The metabolism of cyclophosphamide. Cyclophosphamide is converted to 4-hydroxycyclophosphamide, in equilibrium with its tautomer aldophosphamide, by cytochrome P450 enzymes. Subsequent nonenzymatic processes lead to the formation of phosphoramide mustard and acrolein. Oxidation of 4-hydroxycyclophosphamide and aldophosphamide through enzymes including aldehyde dehydrogenase results in inactive metabolites. Cytotoxic metabolites are shown in bold type.

compared with 8 hours in control subjects, toxicity is not increased, suggesting that exposure to cytotoxic metabolites is not increased and dose modification in liver disease is generally not required.[1]

**Renal Impairment.** Some studies have shown little alteration in drug disposition with no increased toxicity in patients with impaired renal function.[1] In patients with autoimmune disease and a creatinine clearance of 25 to 50 mL/min and 10 to 25 mL/min, exposure to cyclophosphamide increased approximately 40% and 70%, respectively.[5] In clinical practice, initial cyclophosphamide doses are therefore decreased by approximately 30% in patients with moderate to severe renal impairment, and subsequent doses are titrated according to clinical response and effects on the leukocyte (white blood cell) count. Cyclophosphamide is removed by dialysis and is administered after dialysis, or, alternatively, dialysis can be initiated the day after cyclophosphamide administration.[5]

## Clinical Indications

Cyclophosphamide is most commonly used as a remission induction agent for patients with systemic necrotizing vasculitis or Goodpasture's syndrome, for many patients with organ-threatening SLE, and for some patients with autoimmune disease–associated interstitial lung disease and inflammatory eye disease. In SLE, a remission induction course with IV cyclophosphamide followed by maintenance with azathioprine or mycophenolate to minimize cyclophosphamide toxicity is still commonly used to treat severe organ involvement, including lupus nephritis, although remission induction regimens with MMF (discussed in subsequent text) and the B cell depleting biologic agent rituximab have been propagated as effective and safe alternatives to cyclophosphamide.[6] The original National Institutes of Health (NIH) protocol entailed 6 monthly IV infusions with cyclophosphamide, 1 g/m$^2$, and then one infusion every 3 months for at least 24 additional months,[7] whereas the Euro-Lupus protocol used in Europe entailed administration of six IV infusions of 500 mg of cyclophosphamide every 2 weeks followed by azathioprine maintenance (Table 62-2). A comparison with 6 monthly IV infusions of cyclophosphamide, 500 mg/m$^2$, followed by two further infusions of slightly higher doses 3 and 6 months later, along with azathioprine maintenance therapy, resulted in similar rates of the endpoints of end-stage renal disease or doubling of creatinine concentration with up to 10 years of follow-up.[8]

Cyclophosphamide administered as either IV pulse therapy or orally can also be effective in patients with other serious complications of SLE, including central nervous system involvement and thrombocytopenia and interstitial lung disease associated with systemic sclerosis and other autoimmune diseases.[9-11] Several trials have investigated whether IV cyclophosphamide is as effective as oral cyclophosphamide as remission induction therapy for granulomatosus with polyangiitis (GPA). Although early trial results suggested superiority of oral dosing, more recent clinical trial data pointed to equal efficacy but slightly less hematologic toxicity with IV therapy.[12-15] As in lupus nephritis, shorter induction courses of cyclophosphamide have been reported to be effective in GPA and microscopic polyangiitis.[16] Cyclophosphamide has a steep dose-response curve, making it an ideal compound for dose escalation. High doses of cyclophosphamide, with or without stem cell rescue and lymphoablative antibodies or total body irradiation, have been used for severe juvenile idiopathic arthritis (JIA), rheumatoid arthritis (RA), systemic sclerosis, and SLE.[17] With the introduction of effective biologics and new treatment paradigms for RA and JIA, the clinical need for immunoablative treatment in these diseases has waned. Although large series have shown promising results of immunoablative therapy and stem cell rescue in patients with severe SLE, a recent randomized trial showed that standard-dose IV cyclophosphamide was not inferior to high-dose cyclophosphamide *without* stem cell rescue or lymphoablative antibodies.[18] A small phase 2 trial and a larger prospective, randomized phase 3 trial in 156 patients with systemic sclerosis to compare the safety and efficacy of IV pulse cyclophosphamide and immunoablative therapy *with* stem cell rescue, however, showed superior efficacy of the latter on a range of outcome measures including modified Rodnan skin score, functional ability, quality of life, and survival, albeit at the expense of greater toxicity in the first year as a result of infections and cardiopulmonary events.[19,20]

**TABLE 62-2** Lupus Nephritis Treatment Protocols

| |
|---|
| **National Institutes of Health Protocol** |
| Cyclophosphamide: 6× monthly IV 500-750 mg/m$^2$, then maintenance doses every 3 mo until 1 y after remission, or consider alternative remission maintenance treatment with azathioprine or mycophenolate mofetil; dose adjustments on the basis of nadir leukocyte counts and glomerular filtration rate |
| All patients to receive prednisone, 0.5-1 mg/kg/day for 4 wk, decreasing the every-other-day dose each week, if possible, by 5 mg to achieve a prednisone dose of 0.25 mg/kg on alternate days |
| **Euro-Lupus Protocols** |
| *Low-dose* cyclophosphamide: 6× biweekly IV 500 mg |
| *High-dose* cyclophosphamide: 6× monthly IV 500 mg/m$^2$ of body surface area, followed by 2 quarterly pulses with higher dose (+250 mg depending on leukocyte nadir, maximum 1500 mg) |
| All patients to receive: Glucocorticoids: 3× daily IV methylprednisolone, 750 mg, followed by oral 0.5 mg/kg/day of prednisolone (or equivalent) for 4 wk; after 4 wk, tapering of glucocorticoid by 2.5 mg prednisolone every 2 wk; low-dose glucocorticoid therapy (5-7.5 mg prednisolone/day) was maintained at least until mo 30 after inclusion; dose at discretion of treating physician thereafter. Azathioprine: oral, 2 mg/kg daily, starting 2 wk after last cyclophosphamide infusion until mo 30 after inclusion; choice of immunosuppressant at discretion of treating physician thereafter |

IV, Intravenous.

## Dosage and Route of Administration

Typical dosage regimens are presented in Table 62-2. Dosages for IV pulse therapy with cyclophosphamide range from 0.5 to 1 g/m$^2$, and the dosage for oral therapy is 2 mg/kg. The bioavailability of oral cyclophosphamide is excellent.

## Toxicity

### Hematologic

Reversible myelosuppression manifesting as leukopenia and neutropenia is common and dose dependent. Generally,

platelet counts are not affected with IV pulse doses of less than 50 mg/kg, but with long-term oral use, a mild decrease in the platelet count is common. After a single IV dose of cyclophosphamide, the approximate times to nadir and recovery of leukocyte counts are 8 to 14 days and 21 days, respectively.[21] The white blood cell nadir is about 3000 cells/mm$^3$ after a dose of 1 g/m$^2$ (~25 mg/kg) and 1500 cells/mm$^3$ after a dose of 1.5 g/m$^2$. With long-term use, sensitivity to the myelosuppressive effects of cyclophosphamide is increased, and doses usually need to be decreased over time.

### Infection

Infection with a range of common and opportunistic pathogens is a frequent complication. In 100 patients with SLE, infection occurred in 45 patients during treatment with a cyclophosphamide-based regimen and was the primary cause of death in 7 patients.[22] In this study, infection was equally common in patients receiving oral or IV cyclophosphamide and was associated with a white blood cell nadir at some point in treatment of less than 3000/mm$^3$ (55% infection rate vs. 36%). At the time of infection, the average white blood cell count was normal, however.[22] A higher maximal corticosteroid dose was also associated with increased risk of infection. Half of the infections occurred at prednisone doses of less than 40 mg/day, and a quarter of the infections occurred at doses less than 25 mg/day. Lower rates of infection (25% to 30%) have been reported in patients with SLE who received cyclophosphamide in NIH protocols.[23] Oral cyclophosphamide regimens generally pose a greater risk of infection than IV pulse regimens. Serious infections occurred in 41% and 70% of patients with GPA who were treated with pulse IV and daily oral cyclophosphamide, respectively.[12] These rates of infection are higher than rates reported in long-term NIH protocols, in which 48% of 158 patients experienced 140 infections requiring hospitalization.[24] The reported frequency of cyclophosphamide-associated infection varies, probably as a function of the stage and severity of the underlying disease, the degree of cyclophosphamide-induced immunosuppression, and variations in concomitant glucocorticoid regimens. *Pneumocystis jiroveci* pneumonia has been recognized as a preventable, serious opportunistic infection that complicates treatment of systemic vasculitis with regimens using cyclophosphamide and methotrexate. The risk is highest during the remission induction phase and is greater with oral than IV cyclophosphamide regimens.[25] Surprisingly, in two placebo-controlled, randomized clinical trials in persons with scleroderma lung disease, active treatment for 1 year with either oral cyclophosphamide or sequential treatment with prednisolone plus IV cyclophosphamide followed by azathioprine was not associated with more toxicity, suggesting disease-specific differences in toxicity.[10,11]

### Urologic

The bladder toxicities of cyclophosphamide, hemorrhagic cystitis, and bladder cancer are related to route of administration, duration of therapy, and cumulative cyclophosphamide dose. Bladder toxicity, a particular problem with long-term oral cyclophosphamide, is largely due to acrolein, a metabolite of cyclophosphamide. It is commonly accepted that bladder toxicity can be minimized in patients receiving pulse doses of IV cyclophosphamide by administering mesna, a sulfhydryl compound that binds acrolein in the urine and inactivates it.[26] Direct evidence for the effectiveness of mesna in preventing cystitis, however, comes from its use with ifosfamide in patients with cancer and data from animal models. The data from rheumatology series are consistent with a protective effect but are inadequate to come to firm conclusions, which explains differences between national guidelines.[27] The short half-life of mesna renders it suboptimal for the prevention of bladder toxicity in patients receiving daily oral cyclophosphamide, but oral mesna administered three times a day with daily oral cyclophosphamide was associated with a relatively low incidence of bladder toxicity of 12%.[28]

Nonglomerular hematuria, which may range from minor, microscopic blood loss to severe, macroscopic bleeding, is the most common manifestation of cyclophosphamide-induced cystitis.[29] Nonglomerular hematuria occurred at some time in 50% of 145 patients treated with oral cyclophosphamide and was related to the duration of therapy and cumulative cyclophosphamide dose.[29] The risk of bladder cancer was increased 31-fold (95% confidence interval [CI], 13-fold to 65-fold), and bladder cancer had developed in 7 patients (5%) any time between 7 months and 15 years after the initiation of therapy. The cancer was preceded by nonglomerular hematuria in all patients. Six of the seven patients had a cumulative dose of more than 100 g of cyclophosphamide and a duration of therapy of more than 2.7 years. Smokers were at increased risk of hemorrhagic cystitis and bladder cancer.

### Malignancy

Cyclophosphamide increases the risk of malignancies (other than bladder cancer) twofold to fourfold. In the largest study, 119 patients with RA who had been treated with oral cyclophosphamide were followed up for 20 years.[29] In the cyclophosphamide group, 50 cancers occurred in 37 patients, compared with 26 cancers that occurred in 25 of 119 control subjects with RA. Bladder, skin, myeloproliferative, and oropharyngeal malignancies occurred more commonly in the cyclophosphamide group. The risk of malignancies increased with the cumulative dose of cyclophosphamide, and a malignancy developed in 53% of patients who received more than 80 g of cyclophosphamide. Few malignancies have been reported in patients treated with pulse IV cyclophosphamide regimens. Current data do not allow quantification of the long-term risk of malignancy associated with pulse IV cyclophosphamide treatment, but it is likely to be substantially smaller than that associated with oral regimens.

### Reproductive

Cyclophosphamide, when used to treat autoimmune disease, results in significant gonadal toxicity. The risk of sustained amenorrhea after cyclophosphamide therapy has ranged from 11% to 59%.[30] The risk of ovarian failure depends more on the age of the patient and the cumulative dose of

cyclophosphamide than on the route of administration.[30] Patients younger than 25 years receiving six pulses of IV cyclophosphamide had a low frequency of ovarian failure (none of four patients), whereas patients older than 31 years receiving 15 to 24 pulses all had ovarian failure (four of four patients). The use of alkylating agents in male patients leads to azoospermia, and, if the clinical situation allows, referral to a fertility clinic for banking of sperm (or ova in female patients) should be considered before cyclophosphamide treatment. The offspring of adults who underwent cancer chemotherapy in childhood had no increase in genetic disease.[31]

### Pulmonary

Cyclophosphamide-induced pulmonary toxicity occurs in less than 1% of patients. Early-onset pneumonitis 1 to 6 months after exposure to cyclophosphamide may respond to withdrawal of the drug and treatment with corticosteroids. A more insidious, irreversible, late-onset pneumonitis and fibrosis with radiographic findings of diffuse reticular or reticulonodular infiltrates may occur after treatment with oral cyclophosphamide for 1 to 13 years.[32]

### Miscellaneous

A varying degree of reversible alopecia can occur with daily oral and monthly pulse cyclophosphamide. Cardiotoxicity, a dose-limiting adverse effect in oncology, and water intoxication, as a result of inappropriate anti-diuretic hormone secretion, are rare at standard doses.[33] Unusual hypersensitivity reactions include urticaria and anaphylaxis, although the bladder protectant mesna is a more likely cause of allergic responses in patients receiving both drugs.[34,35]

### Strategies to Minimize Toxicity

Strategies to minimize toxicity include adjusting the dose of cyclophosphamide to avoid a significant degree of leukopenia (white blood cell count <3000/mm$^3$ for daily oral therapy or a nadir of <2000/mm$^3$ for pulse IV therapy) and granulocytopenia.[36] The blood count is monitored initially at 1- to 2-week intervals and monthly thereafter in patients taking stable oral doses. To decrease the risk of infection added by concomitant high-dose corticosteroids, the dose of corticosteroids should be reduced after a clinical response has been obtained. Alternate-day administration of glucocorticoids can be considered in the maintenance phase. Oral cyclophosphamide is best administered as a single dose in the morning with the patient drinking plenty of fluids and emptying the bladder frequently to dilute the urinary concentration of acrolein and to minimize the amount of time the bladder is exposed to it. Prophylaxis against *P. jiroveci* pneumonia is often prescribed, particularly during the induction phase when doses of cyclophosphamide and corticosteroids are higher. The use of mesna to prevent bladder toxicity was described earlier. Urinalysis should be performed monthly, and nonglomerular hematuria should be evaluated by a urologist. All patients who receive cyclophosphamide, particularly patients in whom hemorrhagic cystitis develops, are at increased risk of developing bladder cancer, and lifelong surveillance is required with urinalysis, urine cytology, and, if indicated, cystoscopy.[37] Lastly, drugs that are less toxic than cyclophosphamide such as methotrexate, MMF, and rituximab are an option for inducing remission or for remission maintenance in patients with GPA or lupus nephritis.[38,39]

## Pregnancy and Lactation

Cyclophosphamide is a U.S. Food and Drug Administration (FDA) Pregnancy Category D drug. Cyclophosphamide is teratogenic, particularly in the first trimester, and should be avoided during pregnancy and lactation.[40,41] If a patient becomes pregnant while taking (receiving) this drug, the patient should be apprised of the potential hazard to the fetus. Women of childbearing potential should be advised to avoid becoming pregnant.

## Drug Interactions

Cimetidine inhibits the activity of several hepatic enzymes. It has resulted in increased exposure to cyclophosphamide metabolites in a rabbit model.[42] Ranitidine and presumably other H2 receptor antagonists that have little effect on hepatic drug metabolism are not associated with increased cyclophosphamide toxicity.[43] Allopurinol increases the half-life of cyclophosphamide and the frequency of leukopenia.[44] Cyclophosphamide decreases plasma pseudocholinesterase activity and can potentiate the effect of succinylcholine.[45]

# AZATHIOPRINE

## Structure

Azathioprine is a prodrug that is converted to 6-mercaptopurine (6-MP), which involves the removal of an imidazole group.[46] 6-MP is a purine analogue that acts as a cycle-specific antimetabolite chemotherapeutic agent and interferes with the synthesis of nucleotides, thereby inhibiting proliferation of lymphocytes. Azathioprine has a better therapeutic index than 6-MP and has replaced it in the treatment of rheumatic autoimmune disease.

## Mechanisms of Action

The exact mechanism of action of the active thiopurine metabolites of azathioprine in autoimmune disease is unknown. Thiopurine metabolites such as thioguanine nucleotides decrease the de novo synthesis of purine nucleotides by inhibiting amidotransferase enzymes and purine ribonucleotide interconversion and are incorporated into DNA and RNA.[46] The incorporation of thioguanine nucleotides into the nucleic acids of cells is thought to mediate the cytotoxicity of azathioprine, whereas inhibition of purine synthesis may be more important in decreasing cellular proliferation. Leukopenia is unnecessary for immunosuppression. Azathioprine decreases the circulating lymphocyte count, suppresses lymphocyte proliferation, inhibits antibody production, inhibits monocyte production, suppresses natural killer cell activity, and inhibits cell-mediated and humoral immunity.

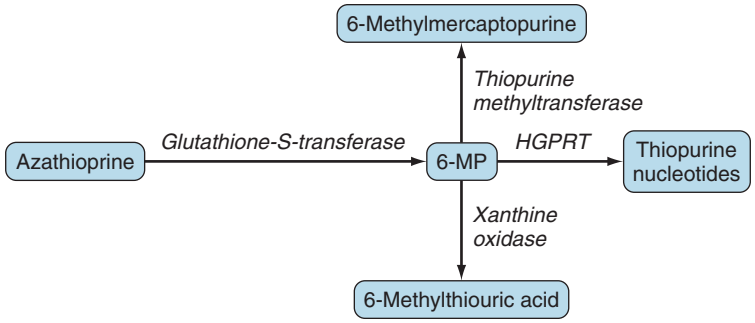

**Figure 62-2** Azathioprine is converted to mercaptopurine (6-MP) enzymatically by glutathione-*S*-transferase and nonenzymatic mechanisms. Xanthine oxidase and thiopurine methyltransferase metabolize 6-MP to the inactive metabolites 6-methylthiouric acid and 6-methylmercaptopurine. Hypoxanthine-guanine-phosphoribosyl-transferase (HGPRT) metabolizes 6-MP to active, cytotoxic thiopurine nucleotides.

## Pharmacology

### Absorption and Distribution

Oral azathioprine is well absorbed and rapidly converted to 6-MP, which is further metabolized to several compounds, including 6-thiourate (Figure 62-2), that are excreted in urine. The plasma half-life of azathioprine is less than 15 minutes, but it is 1 to 3 hours for the active derivative, 6-MP.[47] The bioavailability of azathioprine, measured as the concentrations of mercaptopurine achieved after oral administration, varies. In healthy volunteers, bioavailability ranged from 27% to 83%, with an average of 47%.[47] Mercaptopurine is widely distributed with a volume of distribution of 4 to 8 L/kg.[46]

### Metabolism and Elimination

The metabolism of azathioprine is complex[46,48] and has been simplified in Figure 62-2. Two enzymes, xanthine oxidase and thiopurine S-methyltransferase (TPMT), shunt mercaptopurine metabolites to relatively inactive compounds, whereas other enzymes such as hypoxanthine-guanine-phosphoribosyl-transferase lead to the formation of cytotoxic thiopurine nucleotides. Low TPMT activity or inhibition of xanthine oxidase by drugs such as allopurinol leads to decreased detoxification and increased formation of cytotoxic metabolites after the administration of azathioprine or mercaptopurine. Maximal concentrations of mercaptopurine occur 1 to 3 hours after administration of azathioprine, and the half-life of mercaptopurine is 1 to 2 hours.[47] The half-life of the intra-cellular, active 6-thioguanine nucleotides is estimated to be 1 to 2 weeks, however, and concentrations do not change over the 24-hour dose period in patients receiving daily azathioprine.[49] At conventional rheumatologic doses, approximately 1% of mercaptopurine is excreted unchanged in the urine.[49] Increased toxicity can occur with renal impairment (creatinine clearance <25 mL/min), and a modest dose reduction is usually necessary. The substantial interindividual variability in azathioprine disposition and TPMT activity are more important determinants of sensitivity to azathioprine than renal function.[50] Azathioprine is only slightly dialyzable (10%) through conventional hemodialysis membranes.

### Dosage

Azathioprine is often started at a dose of 1 mg/kg daily, and if this dose is tolerated, it is increased to 2 to 2.5 mg/kg after 2 to 4 weeks. A gradual increase in dose is often better tolerated. The onset of immunosuppressive effects is relatively slow, over several weeks, presumably because the active thioguanine metabolites slowly accumulate intra-cellularly.

## Clinical Indications

In current practice, azathioprine is mainly used in the treatment of connective tissue disease rather than inflammatory joint disease. Azathioprine is less effective than methotrexate in RA and has a slow mode of onset when compared with other disease-modifying anti-rheumatic drugs and biologics. Nevertheless, it remains a treatment option for patients with RA who have refractory disease or as a corticosteroid-sparing agent in persons with organ involvement. Azathioprine is used to treat some patients with lupus nephritis, and although it is more effective than corticosteroids alone, it is not as effective as IV pulse cyclophosphamide to induce remission.[51] It is effective in maintenance therapy, however,[52] even after low-dose cyclophosphamide induction. For other manifestations of SLE, including cutaneous disease, azathioprine is widely used as a glucocorticoid-sparing agent.[53]

Azathioprine in combination with corticosteroids is useful in the treatment of a range of other autoimmune diseases including inflammatory muscle disease, inflammatory eye disease, including Behçet's disease,[54] psoriatic arthritis,[55] reactive arthritis, and various forms of vasculitis. In systemic vasculitis, azathioprine is less effective as a remission-induction agent than cyclophosphamide[16] but is safer as a remission-maintenance and glucocorticoid-sparing drug.[40] However, a small study has shown the efficacy of high-dose (1200 to 1800 mg infusions) monthly azathioprine as initial treatment of GPA and lupus nephritis.[56] Azathioprine is frequently used in persons with systemic sclerosis and overlap syndromes, especially in persons with interstitial lung disease or joint involvement.[11,57]

## Toxicity

### Hematologic

Reversible myelosuppression is dose related but varies among individuals. Low-dose azathioprine (1 to 2 mg/kg/day) rarely results in leukopenia or thrombocytopenia. Pure red cell aplasia is also rare. Severe myelosuppression is uncommon and is caused by low or absent TPMT activity. Decreased TPMT activity leads to a decreased ability to detoxify mercaptopurine and results in increased formation of cytotoxic thioguanine metabolites and clinical toxicity.[58] TPMT activity is polymorphic with a trimodal distribution. Approximately 90% of subjects show high activity, 10% show intermediate activity, and 0.3% (the subjects homozygous for the poorly functional polymorphisms) show very low activity.[59,60] The median TPMT activity in African Americans is approximately 17% lower than in white Americans.[60] The 1 in 300 subjects with low or absent TPMT activity are at great risk of severe azathioprine-induced myelosuppression, which has a delayed but sudden onset, most commonly 4 to 10 weeks after azathioprine has been started.[61] In more than half of all cases of leukopenia in patients receiving azathioprine, the patients have a normal TPMT genotype and phenotype, however.

### Gastrointestinal

Liver test abnormalities occur in 34% of patients but are seldom serious. Serious liver toxicity, severe cholestasis, hepatic veno-occlusive disease, and nodular regenerative hyperplasia and pancreatitis are rare.

### Malignancy

Data regarding the risk of malignancy in patients treated with azathioprine for rheumatologic disease are conflicting. Some studies found an increased risk, particularly of lymphoproliferative malignancies, whereas others did not find an increased risk.[62] A 24-year retrospective study of 358 patients with SLE found no difference in malignancy rates between patients who had and had not received azathioprine, and no lymphomas occurred in the azathioprine group.[58]

### Hypersensitivity

Acute hypersensitivity syndromes, usually occurring within 2 weeks of starting therapy, are rare, with a range of manifestations including shock, fever, rash, pancreatitis, renal failure, and hepatitis.[63]

### Other Toxicities

Infection is less common with azathioprine than with alkylating agents; however, infections with a range of bacterial and nonbacterial pathogens, including herpes zoster and cytomegalovirus, may occur. The rate of infection when azathioprine is administered alone or with low doses of glucocorticoids is approximately 2.5 per 100 person-years of exposure. Maculopapular or urticarial rashes can occur. Eosinophilia and drug fever are rare.

### Strategies to Minimize Toxicity

TPMT activity testing is the most commonly used method to identify patients at risk of serious toxicity. More than 23 variants in the *TPMT* gene, associated with decreased TPMT activity, have been identified, with the TPMT*2, TPMT*3A, and TPMT*3C alleles accounting for most of the intermediate- or low-activity cases. The concordance between TPMT genetics and phenotypes is slightly less than 100%. TPMT activity (phenotype) can be measured directly in red blood cell membranes. Alternatively (e.g., in patients who have undergone blood transfusions), genetic polymorphisms can be identified by polymerase chain reaction. Guidelines for TPMT activity testing vary among different specialties, but it is generally recommended that TPMT status be tested before starting azathioprine therapy. Whether testing is cost-effective and clinically useful when compared with traditional monitoring of white blood cell counts is still a matter of debate.[64-67] In the absence of TPMT testing, administration of a low initial dose and careful monitoring of the white blood cell count in patients starting azathioprine is required. Some authors suggest weekly monitoring during the first 15 weeks of azathioprine treatment.[60] When patients are taking a stable dose of azathioprine, blood counts are monitored monthly and liver function tests are monitored every 3 to 4 months.

## Drug Interactions

One of the most important and potentially fatal drug interactions in rheumatology is the ability of allopurinol to dramatically increase the cytotoxic effects of azathioprine through inhibition of xanthine oxidase–mediated inactivation of mercaptopurine.[68] Various strategies have been used to treat hyperuricemia and gout in patients receiving azathioprine, which is a common clinical problem after transplantation. Reduction of the dose of azathioprine by at least two thirds in patients who also are receiving allopurinol is advocated. However, because myelosuppression can still occur after a 75% reduction in dose, careful monitoring is required.[68] Alternatively, uricosurics such as benzbromarone have been effective and safe,[68] and MMF has been substituted for azathioprine as an alternative immunosuppressant.[69] The combination of azathioprine with several other drugs, including sulfasalazine, ganciclovir, angiotensin-converting enzyme inhibitors, carbamazepine, co-trimoxazole, and clozapine, may also increase the risk of myelosuppression. Azathioprine has been associated with resistance to warfarin in case reports.[70]

## Pregnancy and Lactation

Azathioprine is an FDA Pregnancy Category D drug. Azathioprine crosses the placenta, but drug and metabolite concentrations are lower in the fetal circulation, suggesting placental metabolism.[41,71] Data relating to rheumatologic diseases are limited, and although azathioprine is being used during pregnancy, it is better avoided during pregnancy and lactation if possible.[72] In a prospective observational study in 189 pregnant women treated with azathioprine for various autoimmune conditions, the rate of major malformation was

3.5%, which was similar to that of the general population.[73] Its use was associated with prematurity, however. Azathioprine may be considered in cases where the benefits of disease control in the mother give the best chances of term pregnancy and fetal survival.

# CYCLOSPORINE

## Structure

Cyclosporine is a lipophilic endecapeptide derived from a fungus; it is effective in refractory RA, psoriatic arthritis, SLE, and autoimmune eye disease.

## Mechanism of Action

Cyclosporine impairs production of interleukin (IL)-2 and other cytokines, reducing lymphocyte proliferation. Cyclosporine complexes with cyclophilin, one of a group of cytosolic-binding proteins known as *immunophilins*. This complex binds to and inhibits calcineurin, a serine/threonine phosphatase. Inhibition of calcineurin phosphatase activity prevents the translocation of cytosolic nuclear factor of activated T cells to the nucleus, a translocation that is required for the transcription of genes for cytokines such as IL-2 and for T cell activation (Figure 62-3).[74]

## Pharmacology

Two formulations of cyclosporine are available for oral use: (1) the older, oil-based Sandimmune formulation and (2) the newer, microemulsion Neoral formulation. The active drug, cyclosporine, is identical in both formulations, but the microemulsion formulation results in better bioavailability and less intersubject and intrasubject variability. Neoral or equivalent generic formulations are replacing the Sandimmune formulation of cyclosporine, which is no longer universally available.

### Absorption and Distribution

Cyclosporine is poorly and variably absorbed from the gut, with a bioavailability of approximately 30%. Consumption of a high-fat meal increases absorption. Substantial interindividual (threefold) and intraindividual (twofold) variability exists in cyclosporine disposition.[75] The time to peak concentration (1 to 8 hours) and the elimination half-life (3 to 20 hours) vary. Cyclosporine is lipophilic and widely distributed in body tissues, particularly in the lean body mass.[75] Higher concentrations of cyclosporine are found in red blood cells than in plasma, and whole-blood concentrations are used for monitoring, although monitoring is seldom required in persons with autoimmune diseases. The time to maximal concentration is approximately 25%

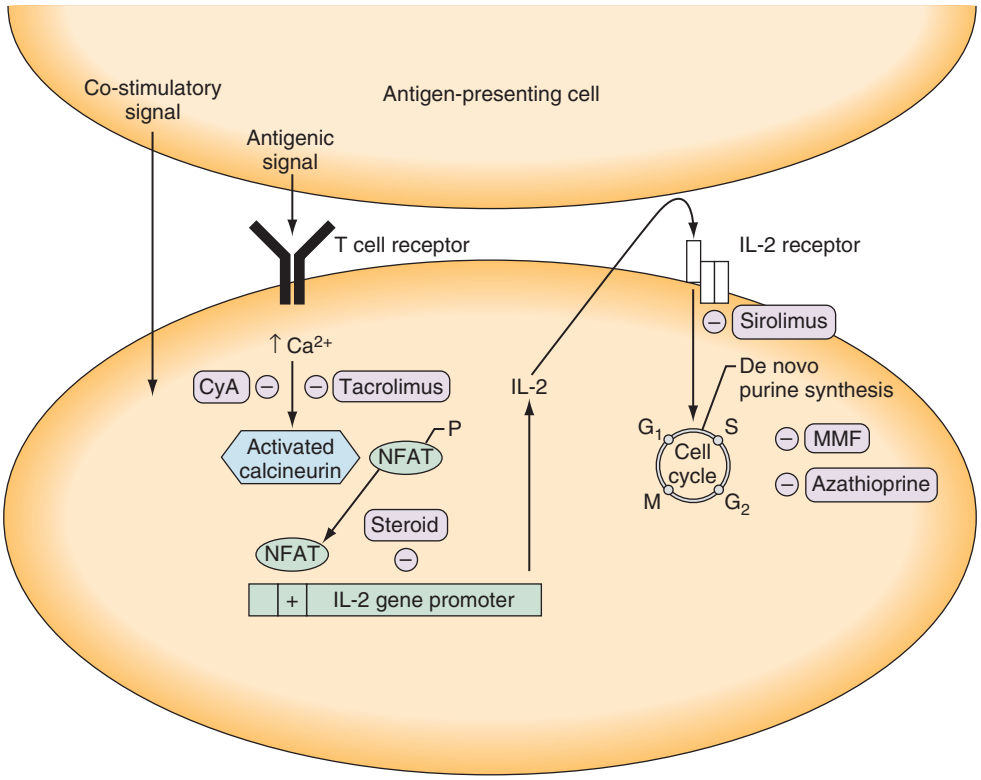

**Figure 62-3** Stages of T cell activation. Multiple targets for immunosuppressive agents. Stimulation of the T cell receptor results in calcineurin activation, a process inhibited by cyclosporine (CyA) and tacrolimus. Calcineurin dephosphorylates nuclear factor of activated T cells (NFAT), enabling it to enter the nucleus and bind to interleukin (IL)-2 promoter. Corticosteroids inhibit cytokine gene transcription in lymphocytes and antigen-presenting cells by several mechanisms. Co-stimulatory signals are necessary to optimize T cell IL-2 gene transcription, prevent T cell anergy, and inhibit T cell apoptosis. IL-2 receptor stimulation induces the cell to enter the cell cycle and proliferate. Signal 3 may be blocked by IL-2 receptor antibodies or by sirolimus, which inhibits second messenger signals induced by IL-2 receptor ligation. After progression into the cell cycle, azathioprine and mycophenolate mofetil (MMF) interrupt deoxyribonucleic acid replication by inhibiting purine synthesis. *(From Denton MD, Magee CC, Sayegh MH: Immunosuppressive strategies in transplantation,* Lancet *353:1083–1091, 1999.)*

shorter, and the maximal cyclosporine concentration and area under the concentration (AUC) curve are increased by approximately 50% with the microemulsion formulation.[76,77] In addition, interindividual and intraindividual variability in cyclosporine disposition are decreased by approximately 50% with the microemulsion formulation.[76,77]

### Metabolism and Elimination

Cyclosporine disposition has two major determinants. First, P-glycoprotein (Pgp), a drug efflux pump, pumps substrates such as cyclosporine out of cells. Pgp, the product of the multidrug resistance gene, is expressed on intestinal epithelial cells and in the liver. Second, cyclosporine is extensively metabolized by the CYP3A enzyme system, which is active not only in the liver but also in intestinal epithelium. Pgp, by limiting drug uptake, and CYP3A4, by assisting drug metabolism in the gut and liver, act to limit the bioavailability of cyclosporine and determine its disposition.[78] Cyclosporine is extensively metabolized to more than 20 metabolites. The rate-limiting step in the elimination of cyclosporine is the formation of metabolites, not their clearance. Cyclosporine elimination is not altered in renal failure; however, because of its nephrotoxicity, cyclosporine is avoided in patients with impaired renal function. Liver disease impairs the excretion of cyclosporine metabolites.

### Dosage

Effective use of cyclosporine requires that appropriate patients be selected for treatment and monitored carefully (Table 62-3). The starting dosage of cyclosporine is 2.5 mg/kg/day, usually administered in divided doses. In obese patients, dosage is based on the approximate ideal body weight. Clinical response is slow, occurring over 4 to 8 weeks, and may be maximal only after 12 weeks or more of treatment. To improve efficacy, the dosage can be increased by 0.5 mg/kg/day at 4- to 8-week intervals to a maximal dosage of 4 mg/kg/day of the microemulsion formulation. If no clinical response occurs in 4 to 6 months, cyclosporine should be discontinued. In patients whose disease is well controlled, the dosage of cyclosporine can be decreased by 0.5 mg/kg/day at 4- to 8-week intervals to determine the minimal effective dose for the individual patient. In patients receiving the older Sandimmune formulation of cyclosporine who convert to the microemulsion formulation, a 1:1 dose conversion is generally used. Because of the greater and more predictable bioavailability of the microemulsion formulation, however, a greater exposure to cyclosporine is likely. Blood pressure (BP) and creatinine should be monitored initially at 2-week intervals after the conversion, and the dose of cyclosporine should be decreased if required.

**TABLE 62-3** Clinical Use of Cyclosporine in Rheumatic Disease

| |
|---|
| Select appropriate patients |
| Contraindications:<br>Current or past malignancy other than basal cell carcinoma, renal impairment, uncontrolled hypertension, or hepatic dysfunction |
| Cautions:<br>Elderly age, obesity, controlled hypertension, premalignant lesions, drugs that interact with cyclosporine, pregnancy |
| Obtain ≥2 creatinine concentrations before starting cyclosporine, and average these to provide baseline creatinine value |
| Start low—cyclosporine 2.5 mg/kg/day in divided doses |
| Stay low—maximum 4 mg/kg/day (microemulsion formulation) |
| Monitor blood pressure and creatinine initially every 2 wk for 3 mo, then monthly if stable |
| If serum creatinine increases >30% above patient's baseline, reduce dosage of cyclosporine by 1 mg/kg/day; recheck serum creatinine in 1-2 wk, and temporarily discontinue cyclosporine if creatinine remains >30% above baseline |
| When creatinine level returns to within 15% of baseline, cyclosporine can be restarted at a lower dosage |

## Clinical Indications

Cyclosporine is effective in the treatment of RA as a single agent and in combination with methotrexate[79] or hydroxychloroquine, but it is used less commonly now because of the availability of more effective and safer treatment options early in the course of RA.[80] Nevertheless, it can still be a useful drug in refractory RA.[81] Cyclosporine can increase mean peak plasma methotrexate levels and AUC by about 20%,[82] which may contribute to the efficacy of the combination. Data comparing the efficacy and safety of cyclosporine with other disease-modifying anti-rheumatic drugs over long periods and in a large number of patients are limited. Cyclosporine is effective for the skin and joint manifestations of psoriasis.[83] Fewer data are available regarding the use of cyclosporine in other rheumatic diseases. In uncontrolled, small studies in persons with SLE,[84] cyclosporine has been reported to improve disease activity, have a glucocorticoid-sparing effect, and improve proteinuria, thrombocytopenia, and leukopenia. The efficacy of cyclosporine as a steroid-sparing drug was confirmed in a randomized clinical trial in patients with severe SLE, but it was not found to be more effective or safer when compared with azathioprine.[85] Cyclosporine has also been reported to be effective in small series of cases in many other autoimmune conditions including pyoderma gangrenosum, Behçet's disease, maintenance therapy of anti-neutrophil cytoplasmic antibody–associated vasculitis, and macrophage-activation syndrome in juvenile RA.[86]

## Toxicity

### Hypertension

Hypertension occurs in approximately 20% of patients with autoimmune disease who receive treatment with cyclosporine. The magnitude of increase in BP is usually mild but clinically significant because it increases the risk of stroke, myocardial infarction, heart failure, and other adverse cardiovascular events associated with elevated BP.[87] The hypertension should be controlled by reducing the dose of cyclosporine or by anti-hypertensive drug therapy.[88]

### Nephrotoxicity

Virtually all patients who take cyclosporine have a small but measurable decrease in renal function that is reversible after

cyclosporine is discontinued. Serum creatinine concentrations have increased approximately 20% in 6- to 12-month clinical trials, but few patients have had to withdraw because of this outcome.[89] Long-term data regarding renal function in patients with RA who are treated with cyclosporine are limited. In one 12-month study, an increase in serum creatinine of more than 30% occurred in 50% of patients; half of these patients responded to cyclosporine dose reduction and half did not, requiring discontinuation of the drug.[88] The small increase in serum creatinine observed in most studies occurs mainly during the first 2 to 3 months of treatment, and then creatinine remains relatively stable over 12 months.[88,89] However, other data suggest that over periods of treatment longer than 1 year, many patients, who over the first year had a stable, acceptable increase in creatinine concentration, subsequently have an increase in creatinine to more than 30% of baseline that is not controlled by cyclosporine dose reduction; such patients must discontinue treatment.[90] Preventable risk factors for cyclosporine-induced nephrotoxicity are a high dosage of cyclosporine (>5 mg/kg/day) and an increase in serum creatinine concentration of more than 50% of the baseline value. The risk of cyclosporine nephropathy is low in patients treated according to the clinical guidelines (see Table 62-3).[91] Renal biopsy specimens in 11 patients with RA who received cyclosporine (average dosage, 3.3 mg/kg/day) for 26 months and had an average increase in serum creatinine of 31% showed no significant cyclosporine-induced renal changes.[92]

### Gastrointestinal

Gastrointestinal upset is common but usually mild and transient. A few patients discontinue cyclosporine therapy for this reason, however.

### Malignancy

In transplant recipients, cyclosporine use has been associated with an increased risk of skin cancer and lymphoma. In 208 patients with RA who were treated with cyclosporine for an average of 1.6 years, the incidence of malignancy and mortality was similar to that of control subjects with RA,[93] but a recent meta-analysis on the risk of immunomodulatory drugs in persons with RA, psoriasis, and psoriatic arthritis did find an increased risk of nonmelanoma skin cancer in patients treated with cyclosporine.[94] Epstein-Barr virus–induced B cell lymphoma, which may be reversible when cyclosporine is discontinued, has been reported in a few patients receiving cyclosporine for a variety of indications.

### Other Toxicities

Other adverse effects that are common but usually of minor significance include hypertrichosis, gingival hyperplasia, tremor, paresthesia, breast tenderness, hyperkalemia, hypomagnesemia, and an increase in serum uric acid.[88] Cyclosporine may result in a clinically insignificant increase in alkaline phosphatase concentrations but does not increase the frequency of abnormal transaminase concentrations in patients also receiving methotrexate.[95]

### Strategies to Minimize Toxicity

Because cyclosporine may increase liver enzymes, as well as potassium, uric acid, and lipid concentrations, and decrease magnesium concentrations, it is prudent to measure these enzymes and concentrations before, and occasionally after, initiating therapy. At least two, and preferably more, recent normal BP and serum creatinine determinations should be obtained before starting treatment.

Many patients with RA have low serum creatinine concentrations, and it is important not to overlook significant cyclosporine-induced elevations in serum creatinine, which may remain within the normal laboratory reference range. If a patient has a baseline creatinine level of 0.6 mg/dL and, after administration of cyclosporine, the level increases to 0.9 mg/dL (which is still in the normal range), this change represents a 50% increase above baseline and requires dose reduction. Cyclosporine concentrations are not useful predictors of efficacy or toxicity in rheumatic diseases and are not routinely performed. Cyclosporine trough concentrations, which are measured approximately 12 hours after the last dose, can be useful if concerns exist about compliance or unusual drug disposition in individual patients.

## Pregnancy and Lactation

Cyclosporine is an FDA Pregnancy Category C drug. Pregnancy outcomes in transplant recipients receiving cyclosporine-based and noncyclosporine-based regimens are similar. Cyclosporine use in pregnancy is not recommended, however, unless the potential benefit exceeds the potential risk to the fetus. Breastfeeding should be avoided.

## Drug Interactions

Cyclosporine and tacrolimus, because of the influence of Pgp and CYP3A4 enzyme activity on their disposition, have many clinically important drug interactions (Table 62-4).[96,97]

**TABLE 62-4** Clinically Important Drug Interactions with Cyclosporine*

| |
|---|
| **Increased Cyclosporine Concentrations** |
| Erythromycin, clarithromycin |
| Azole antifungals: ketoconazole, fluconazole, itraconazole |
| Calcium channel antagonists: diltiazem, verapamil, amlodipine† |
| Grapefruit juice |
| Others: amiodarone, danazol, allopurinol, colchicine |
| **Decreased Cyclosporine Concentrations** |
| Inducers of hepatic enzymes: rifampicin, phenytoin, phenobarbitone, nafcillin, St John's wort |
| **Increased Cyclosporine Toxicity** |
| Increased renal toxicity with aminoglycosides, quinolone antibiotics, amphotericin B, (?) nonsteroidal anti-inflammatory drugs, (?) angiotensin-converting enzyme inhibitors |
| **Cyclosporine Increasing Toxicity of Another Drug** |
| Increased risk of myopathy and rhabdomyolysis with lovastatin and other statins |
| Increased risk of colchicine neuromyopathy and toxicity |
| Increased digoxin concentrations |
| Increased risk of hyperkalemia with $K^+$-sparing diuretics and $K^+$ supplements |

*Most interactions with cyclosporine are also likely to apply to tacrolimus.
†Data are conflicting about whether amlodipine does or does not increase cyclosporine concentrations.

Many drugs such as erythromycin, azole antifungal drugs, and some calcium channel antagonists that inhibit CYP3A4 (inhibiting the metabolism of cyclosporine) also inhibit Pgp. Drug interactions mediated by these dual mechanisms may result in a twofold to fivefold increase in cyclosporine concentrations. Azithromycin, in contrast to erythromycin and clarithromycin, seems unlikely to alter cyclosporine levels. The plasma concentrations and clinical toxicity of several statin lipid-lowering agents are increased substantially by cyclosporine, but the pharmacokinetics of fluvastatin and pravastatin, because they are not metabolized primarily by CYP3A4, are altered less by cyclosporine.[98] Nevertheless, the pravastatin AUC curve, a measure of drug exposure, was five times higher in patients also receiving cyclosporine.[99] Of the calcium channel antagonists, diltiazem, nicardipine, and verapamil increase cyclosporine concentrations; nifedipine and amlodipine have variable effects; and isradipine and nitrendipine do not generally affect concentrations.[100] It is controversial whether nonsteroidal anti-inflammatory drugs (NSAIDs) increase cyclosporine nephrotoxicity. In many clinical studies, cyclosporine and NSAIDs have been safely co-administered[79,101]; however, increased cyclosporine-associated nephrotoxicity with NSAIDs has been reported. Currently, many patients starting cyclosporine also take an NSAID. If the creatinine increases, in addition to decreasing the dose of cyclosporine, discontinuation of the NSAID may be tried. Grapefruit juice increases plasma concentrations of cyclosporine, so patients should be warned to avoid consuming grapefruit.

## TACROLIMUS (FK506)

### Structure

Tacrolimus, previously known as FK506, is a macrolide derived from an actinomycete and is widely used in organ transplantation as an alternative to cyclosporine. Studies in rheumatic autoimmune disease are less advanced.

### Mechanisms of Action

Tacrolimus is about 100 times more potent than cyclosporine and, although structurally different, is also a calcineurin inhibitor. Tacrolimus binds to an intra-cellular binding protein (FK binding protein), and this drug-immunophilin complex, in association with calcineurin, suppresses transcription of cytokines such as IL-2, inhibiting the early steps of T lymphocyte activation (see Figure 62-3).[74]

### Pharmacology

Absorption of tacrolimus after oral administration is poor and highly variable (range, 4% to 93%; average, 25%).[102] Tacrolimus is lipophilic, is widely distributed in tissues, and is almost completely metabolized, with an elimination half-life of 5 to 16 hours.[103] As with cyclosporine, Pgp and CYP3A4 in the liver and gut are important determinants of the metabolism and disposition of tacrolimus. Drugs that inhibit CYP3A4 or Pgp can increase tacrolimus concentrations (see Table 62-4).[102] Impaired hepatic function, but not impaired renal function, increases tacrolimus concentrations.[103]

### Dosage

Tacrolimus is not routinely used for rheumatologic conditions. Different dosages have been used in clinical studies (see the next paragraph).

### Clinical Indications

Tacrolimus has been studied in a number of rheumatic conditions with variable success. In RA, tacrolimus showed only modest efficacy, and with the availability of a plethora of effective conventional and biologic disease-modifying anti-rheumatic drugs, the need for a novel immunosuppressant such as tacrolimus has waned.[104,105] Topical 1% tacrolimus has been used with moderate success in patients with resistant skin disease resulting from SLE, subacute cutaneous lupus erythematosus, and discoid lupus erythematosus.[106] A large open-label, randomized, controlled trial in 150 patients with biopsy-confirmed active lupus nephritis showed that remission induction with tacrolimus (0.6 mg/kg/day) was not inferior to MMF (2-3 g/day) when given with prednisolone (0.6 mg/kg/day) for 6 weeks and followed by azathioprine maintenance, with major infectious episodes occurring in 5.4% versus 9.2% of patients, respectively.[107] In a retrospective study in patients who had interstitial lung disease associated with polymyositis or dermatomyositis, patients treated with tacrolimus in addition to conventional therapy had a significantly improved survival compared with patients who were treated with conventional therapy alone.[108]

### Toxicity

The adverse effects of tacrolimus are dose related and include nephrotoxicity, hypertension, hyperkalemia, hyperuricemia, tremor, hyperglycemia, and gastrointestinal intolerance.[102] Among patients with RA who took 3 mg of tacrolimus daily for more than 1 year, 59% experienced an adverse effect, probably or possibly due to the drug, including diarrhea (15%); nausea (10%); tremor (9%); headache (9%); abdominal pain (8%); increased creatinine (7%); hypertension (5%); and pneumonia, pancreatitis, hyperglycemia, and diabetes mellitus (all <1%). A creatinine increase of greater than 30% from baseline to the end of the study was found in 40%.[109]

## MYCOPHENOLATE MOFETIL

### Structure

MMF, a prodrug, is the inactive 2-morpholinoester of mycophenolic acid, which is hydrolyzed to the active mycophenolic acid (MPA), an antibiotic with immunosuppressive effects.[110]

### Mechanism of Action

Two pathways exist for the synthesis of guanine nucleotides: the de novo pathway and the salvage pathway. MPA reversibly inhibits inosine monophosphate dehydrogenase, a crucial enzyme for the de novo synthesis of guanosine purines.[110,111] Lymphocytes, in contrast to many other cells,

are critically dependent on the de novo purine synthesis pathway and are a relatively selective target for MPA, accounting for the ability of the drug to inhibit reversibly B cell and T cell proliferation without myelotoxicity.[112] MPA results in decreased guanine synthesis and decreased DNA synthesis, decreased lymphocyte proliferation, altered microRNA expression, and decreased antibody production.[111-114] MPA also inhibits proliferation of fibroblasts, endothelial cells, and arterial smooth muscle cells and prevents deposition and contraction of collagen, extra-cellular matrix proteins, and smooth muscle actin.[115]

## Pharmacology

MMF is rapidly and completely absorbed and de-esterified to the active MPA, which is highly (98%) protein bound. Most MPA (>99%) is found in plasma, with little in cells; most is glucuronidated to the poorly active, stable phenolic glucuronide, which is eliminated in the urine (Figure 62-4).[116] Minor metabolites, some of which may be active, have also been described. Peak levels of MPA occur 1 to 2 hours after administration, and secondary peaks, thought to be due to enterohepatic circulation, can be seen. The half-life of MPA is 16 hours.[116] MPA concentrations may vary fivefold to tenfold in persons receiving the same dose.[117] A small amount of this variability may be due to genetic variation in uridine-glucuronosyltransferase enzymes.[118] Renal disease and liver disease have relatively minor effects on the disposition of the active drug, MPA. Generally, dosage adjustments are not required,[116] but because free MPA concentrations are approximately doubled in patients with severe renal impairment (creatinine clearance <20 to 30 mL/min),[119] they may be necessary sometimes. A retrospective study in 16 patients with lupus nephritis showed that concentration-controlled dose adjustments with a target MPA-AUC (from intake until 12 hours after ingestion) of 60 to 90 mg*h/L was associated with optimized MPA exposure and excellent renal outcome at 12 months, although adverse effects were reported in one third of patients, resulting in a switch to azathioprine in two patients.[120] Another observational study also pointed to the potential benefits of therapeutic monitoring in 34 patients with lupus nephritis when dosing was adjusted to achieve an AUC of 30 to 60 mg*h/L.[121] In this study MPA exposure was not associated with adverse events, and patients with an AUC of 30 mg*h/L or greater had a greater renal response at 1 year. The major glucuronide metabolite of MPA accumulates in patients with impaired renal function and may cause increased gastrointestinal adverse effects. Because MPA is highly protein bound, it is not cleared by hemodialysis.[122]

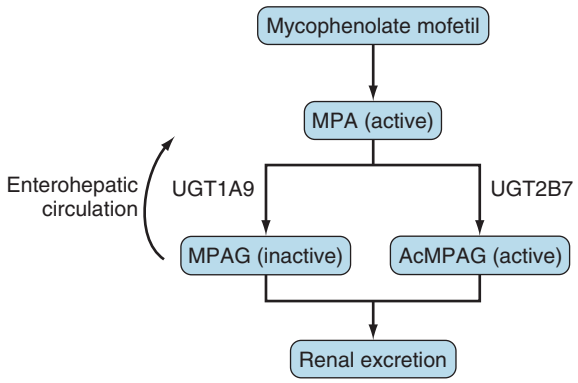

**Figure 62-4** Mycophenolate mofetil is converted to mycophenolic acid (MPA) and is subsequently metabolized to its glucuronide (Glu) conjugates, MPAG and AcMPAG, by different isoforms of UDP glucuronidyl transferases (UGT) in the liver. Pathways of enterohepatic circulation of MPA via the glucuronide conjugate metabolites are shown. The majority of MPAG is excreted in urine.

## Toxicity

MMF is generally well tolerated. The most common adverse effects are gastrointestinal, such as diarrhea, nausea, abdominal pain, and vomiting. Occasional infections, leukopenia, lymphocytopenia, and elevated liver enzymes can occur. Of 54 patients with SLE treated with MMF over a 3-year period, 16% withdrew because of adverse events, with 73% continuing treatment at 12 months.[123] In patients with lupus nephritis, diarrhea was more common and serious infections were less common with MMF than with cyclophosphamide.[41] Enteric-coated mycophenolate sodium and MMF have similar rates of adverse effects.[124] Opportunistic infections, including one that was fatal, occurred in 3 of 10 patients with idiopathic dermatomyositis who were treated with glucocorticoids and MMF.[125]

## Dosage

Effective daily dosages of MMF range from 0.5 to 1.5 g twice a day. In 71 patients with lupus nephritis, the initial dose was 1 g/day with a target of 3 g/day. The mean maximal dose was 2680 mg/day, and 63% of patients tolerated 3 g/day.[39]

## Clinical Indications

MMF is used as a safer alternative to cytostatic agents in the treatment of several rheumatic diseases, notably SLE,[126] systemic sclerosis,[127] vasculitis,[128] and inflammatory muscle disease.[125,129] In a 24-week study in persons with lupus nephritis, mycophenolate was more effective than monthly pulse cyclophosphamide, with a failure rate (without complete or partial remission at 24 weeks, plus those who stopped treatment for any reason) of 34 of 71 (47.9%) compared with 48 of 69 in the cyclophosphamide group (69.6%; $P = 0.01$).[39] In a systematic review of four trials involving 618 patients, MMF was not superior to cyclophosphamide for renal remission, and there was no significant difference for adverse events (infections, leukopenia, gastrointestinal symptoms, herpes zoster, end-stage renal disease, and death) except for a lower incidence of alopecia and amenorrhea with the use of MMF compared with cyclophosphamide.[130] Notwithstanding its appeal as a safer alternative to cyclophosphamide for remission induction therapy of lupus nephritis, MMF is most commonly used for maintenance therapy of lupus nephritis, although systematic reviews comparing its efficacy and safety with azathioprine have not yielded consistent results.[131,132] A study on repeat kidney biopsies in 30 patients with lupus nephritis failed

to detect differences between azathioprine and MMF as maintenance therapy after a short course of IV cyclophosphamide.[133] MMF is an alternative remission induction agent for patients with anti-neutrophil cytoplasmic antibody–associated vasculitis and evidence of low disease activity and who are not at risk of experiencing organ damage.[134] MMF was slightly less effective than azathioprine in maintaining remission, however.[134a] In seven patients with myositis, six had a good clinical and biochemical response to mycophenolate,[129] an observation that was confirmed in another study in six patients who had refractory myositis.[135] In addition, in three studies in patients who had interstitial lung disease associated with dermatomyositis ($n$ = 4) or other connective tissue diseases, including RA ($n$ = 10) and systemic sclerosis ($n$ = 13), MMF was effective in improving signs and symptoms of lung disease.[136-138] MMF may be useful as an alternative immunosuppressant to azathioprine, particularly in patients with gout who require therapy with allopurinol because, in contrast to azathioprine, it does not seem to interact significantly with allopurinol.[72,112] Mycophenolate, 1 g twice daily, was not more effective than placebo in two clinical trials involving 443 patients with refractory RA[139] as assessed with ACR20 responses, and a larger mycophenolate-cyclosporine trial was stopped prematurely. Treatment-related adverse events were experienced by 51.6%, 73.1%, and 36.1% of patients receiving MMF, cyclosporine, and placebo, respectively. Hypertension, increased serum creatinine, muscle cramps, hirsutism, and hypertrichosis were more than twice as common with cyclosporine as with MMF. In all three trials the incidence of serious adverse events with MMF was 12.1% (compared with 11.3% and 7.5% for cyclosporine and placebo, respectively). Although mycophenolate is used in psoriasis as an effective alternative to methotrexate, there are only anecdotal reports of its utility in persons with psoriatic arthritis.

### Pregnancy and Lactation

MMF is an FDA Pregnancy Category C drug. Mycophenolic acid is associated with miscarriage and congenital malformations when used during pregnancy, and therefore it should be avoided whenever possible by women trying to conceive. Switching from MMF to azathioprine in 19 patients with SLE did not result in deterioration of global disease activity, and another study in 54 patients with SLE who had quiescent lupus nephritis showed that replacing MMF with azathioprine rarely leads to renal flares, while pregnancy outcomes were favorable.[140,141] MMF is transferred into the mother's milk, and extreme caution should be used in women with childbearing potential and lactating mothers.

### Drug Interactions

Because MPA is glucuronidated and is not metabolized by CYP oxidation, there are few clinically significant drug interactions. Antacids reduce bioavailability by approximately 15%, and cholestyramine reduces bioavailability by approximately 40%.[142] Rifampin treatment reduced MPA concentrations twofold to threefold.[143] Co-administration with azathioprine is not recommended.

## CONCLUSION

Immunosuppressive drugs are key therapeutic tools in the management of many rheumatic diseases. They include alkylating agents such as cyclophosphamide and purine analogue cytotoxic drugs such as azathioprine with a long history of clinical use in rheumatology, as well as noncytotoxic immunosuppressants such as MMF. In contrast to extra-cellular, exquisitely targeted therapeutics represented by biologics, our understanding of the in vivo mechanism of action of immunosuppressive drugs is still limited. In contrast, their potential efficacy and safety profiles are generally well known, and serious toxicities can usually be prevented by careful monitoring of laboratory tests for white blood cell counts, liver and renal function, and electrolytes. Nevertheless, vigilance is required, because the risk of (opportunistic) infection is increased.[144,145] As a general rule, combination therapy of the different immunosuppressants discussed earlier should be avoided. The individual response to immunosuppressive therapy can be highly variable, and decisions to continue a chosen immunosuppressant should be revisited on a regular basis, weighing the benefits and adverse effects.

CHAPTER 63

# Anti-cytokine Therapies

Zuhre Tutuncu • Arthur Kavanaugh

**KEY POINTS**

- Inhibiting a single key cytokine can be effective in treatment of autoimmune and inflammatory diseases.
- Most patients with rheumatoid arthritis (RA) have at least a partial response to treatment with tumor necrosis factor (TNF) inhibitors, with some patients achieving quite significant improvements in the signs and symptoms of disease.
- Maintaining clinical efficacy with TNF inhibitors usually requires continued therapy. However, there might be a window of opportunity in the early stage of RA or for patients achieving very low levels of disease activity for inducing long-term remission.
- Treatment with TNF inhibitors significantly decreases radiographic damage, improves quality of life, and helps preserve functional status.
- Combination of a TNF inhibitor with methotrexate achieves additive benefits.
- TNF inhibitors have also proven highly effective in treating patients with ankylosing spondylitis, psoriatic arthritis, psoriasis, Crohn's disease, ulcerative colitis, and juvenile idiopathic arthritis.
- TNF inhibitors have been ineffective in the treatment of patients with vasculitis (granulomatosis with polyangiitis and giant cell arteritis).
- Interleukin (IL)-6 inhibition is an effective therapy in RA, with similar improvement in signs and symptoms to treatment with TNF inhibitors as well as in disease progression.
- Although IL-1 inhibition is generally less effective in RA than TNF inhibition, this approach can be highly effective in certain autoinflammatory conditions (e.g., periodic fever syndromes).
- Combination biologic therapy appears to increase the risk of side effects, such as infection, without additional benefits.

In recent years, discoveries that show the immunopathophysiologic basis of rheumatic diseases, combined with biopharmaceutical developments, have introduced biologic therapeutics. These agents target specific components of the immune response that are dysregulated and are thought to be central to the cause and sustenance of the disease process. In the rheumatoid synovium, for example, substantial evidence has been found of upregulation of key proinflammatory cytokines, such as tumor necrosis factor (TNF), interleukin (IL)-1, IL-6, and others.[1,2] Agents that target these key mediators, such as TNF, have considerable efficacy in the treatment of patients with rheumatoid arthritis (RA) and other systemic inflammatory disorders. The perception of both physicians and patients toward antirheumatic treatment has been altered by the ability of TNF and other cytokine inhibitors to not only to improve the signs and symptoms of disease, but also to preserve functional status and quality of life, and to inhibit disease progression. Moreover, their success has led to research into the targeting of other cytokines relevant to the pathogenesis of autoimmune disorders. In this chapter, we focus on therapeutic agents that target TNF, IL-1, and IL-6.

## TUMOR NECROSIS FACTOR INHIBITORS

TNF plays a central role in the pathogenesis of RA and other inflammatory disorders. Although it can be produced by numerous cell types, in inflammatory conditions such as RA, TNF is produced largely by activated macrophages. Human TNF is synthesized and expressed as a 26 kDa transmembrane protein on the plasma membrane and is cleaved by a specific metalloproteinase (TNF-converting enzyme). After proteolytic cleavage, TNF is converted to a 17 kDa soluble protein, which oligomerizes to form the active homotrimer. The actions of TNF are mediated through two structurally distinct receptors: TNF-RI (55 kDa; CD120a) and TNF-RII (75 kDa; CD120b).[3] The two receptors differ in their binding affinities, signaling properties, and primary functions.[3,4] The binding of TNF to its receptor initiates several signaling pathways. Signaling cascades include the activation of transcription factors (e.g., nuclear factor-κB [NF-κB]), protein kinases (intra-cellular enzymes that mediate cellular responses to inflammatory stimuli, such as c-Jun N-terminal kinase [JNK] and p38 mitogen-activated protein [MAP] kinase), and proteases (enzymes that cleave peptide bonds, such as caspases).

TNF may contribute to the pathogenesis of RA through myriad mechanisms, including induction of other proinflammatory cytokines (e.g., IL-1, IL-6) and chemokines (e.g., IL-8); enhancement of leukocyte migration by increasing endothelial layer permeability and adhesion molecule expression and function; activation of numerous cell types; and induction of the synthesis of acute phase reactants and other proteins, including tissue-degrading enzymes (matrix metalloproteinase enzymes) produced by synoviocytes or chondrocytes. The pivotal role of TNF in mediating such diverse inflammatory activities provided the rationale for targeting this cytokine in systemic inflammatory diseases.[5]

Initially, animal studies proved that inhibition of TNF with monoclonal antibodies or soluble TNF-R constructs ameliorated the signs of inflammation and prevented joint destruction.[6] Subsequently, studies in humans confirmed the substantial efficacy of these compounds.

Currently, five anti-TNF agents are potentially available for clinical use: infliximab, a chimeric anti-TNF monoclonal antibody; etanercept, a soluble dimeric p75-TNF-R/Fc fusion construct; adalimumab, a human anti-TNF monoclonal antibody; golimumab, a human anti-TNF monoclonal antibody; and certolizumab pegol, a Fab fragment of a recombinant, humanized anti-TNF monoclonal antibody linked to a 40 kDa polyethylene glycol (PEG) moiety. Additional agents, including biosimilars, will potentially be available in the near future. For each agent, initial assessment in open-label studies of patients with RA was followed by double-blind, placebo-controlled, randomized clinical trials. Typically, early studies included patients with very active disease that was relatively chronic and refractory. Driven by success in the most difficult populations, studies of all TNF inhibitors have also been performed in patients with early RA. Most studies included patients whose disease remained active despite concurrent use of methotrexate (MTX); some studies assessed the efficacy of a drug as monotherapy. Building on the efficacy achieved in RA, TNF inhibitors have been tested in other inflammatory arthritides, including psoriatic arthritis and ankylosing spondylitis. Moreover, these agents have been studied in other autoimmune conditions, such as Crohn's disease, ulcerative colitis, psoriasis, uveitis, and others.

Although all five available agents are macromolecule TNF inhibitors, some pharmacologic and pharmacodynamic differences among them have been noted.[7] The monoclonal antibodies infliximab, adalimumab, golimumab, and certolizumab pegol are specific for TNF, whereas etanercept binds both TNF and lymphotoxin-α (LT-α; previously referred to as *lymphotoxin*). Given intravenously, infliximab has a high peak concentration (Cmax) followed by steady-state elimination, whereas etanercept, adalimumab, golimumab, and certolizumab pegol, because they are given subcutaneously, have "flatter" pharmacokinetic profiles. With the exception of certolizumab pegol, these agents are capable of affecting Fc-mediated functions, such as complement-dependent cytolysis and antibody-dependent cell-mediated cytotoxicity, and all bind to both soluble and membrane forms of TNF, although some relative differences in affinity may be noted. Other differences, such as effects on cytokine secretion, have been observed in some in vitro studies.[8] Data on apoptosis have been somewhat discrepant. In patients with RA, both the anti-TNF monoclonal antibody infliximab and the soluble receptor construct etanercept can induce apoptosis in synovial macrophages.[9] However, in patients with Crohn's disease, etanercept was not clinically effective at the doses studied and did not induce apoptosis. In contrast, the anti-TNF monoclonal antibodies infliximab and adalimumab were clinically effective and induced apoptosis in highly activated lymphocytes.[10] However, certolizumab pegol is effective in Crohn's disease and does not induce apoptosis. The extent to which these potential differences among TNF inhibitors correlate with any specific aspects of efficacy or toxicity remains to be established.

## Infliximab

### Structure

Infliximab is a chimeric mouse-human monoclonal antibody composed of constant regions of human immunoglobulin (Ig)G1κ coupled to the variable regions of a high-affinity neutralizing murine anti–human TNF antibody. The resulting construct is approximately 70% human (Figure 63-1).

### Pharmacokinetics

Clinical pharmacology studies demonstrate that infliximab has a dose-dependent pharmacokinetic profile following infusions of 1 to 20 mg/kg. In combination therapy with MTX (7.5 mg once a week), serum infliximab concentrations tend to be slightly higher than when administered alone.[11] Infliximab behaves in a consistent manner across different demographic groups (including pediatric vs. adult patients) and among patients with different diseases of varied severity. The half-life of infliximab is approximately 8 to 9.5 days at the 3 mg/kg dose, although longer values have been reported for higher doses. The volume distribution of infliximab at steady state (3 to 5 L) is independent of dose, suggesting a predominantly intravascular distribution. Concomitant use of MTX results in an increase in the area under the curve of infliximab of approximately 25% to 30%.

### Drug Dose

The typical initial dose of infliximab in RA is 3 mg/kg given as an intravenous (IV) infusion in combination with MTX, followed by doses 2 and 6 weeks after the first infusion, then every 8 weeks thereafter. Some RA patients have received infliximab in combination with disease-modifying antirheumatic drugs (DMARDs) other than MTX or as monotherapy. For patients who have an incomplete response, dosing may be increased as high as 10 mg/kg, or the drug may be administered as often as every 4 weeks. In the clinic, increasing the dose of infliximab or decreasing the interval of administration is not an uncommon practice; however, it is not clear to what extent such changes achieve clinical improvements. For patients with psoriatic arthritis and ankylosing spondylitis, the recommended dose is 5 mg/kg, with or without MTX, at 0, 2, and 6 weeks, then every 8 weeks.

## Etanercept

### Structure

Etanercept is formed by the linkage of two soluble p75 TNF-R extra-cellular domains to the Fc portion of human $IgG_1$ (see Figure 63-1). The resultant molecule binds both TNF and LT-α with high affinity and specificity. The TNF-R domains in etanercept bind to two of the three receptor binding sites on the TNF trimer, thus blocking the ability of TNF to interact with cell-bound TNF-R—a prerequisite for signal transduction (see Figure 63-1).

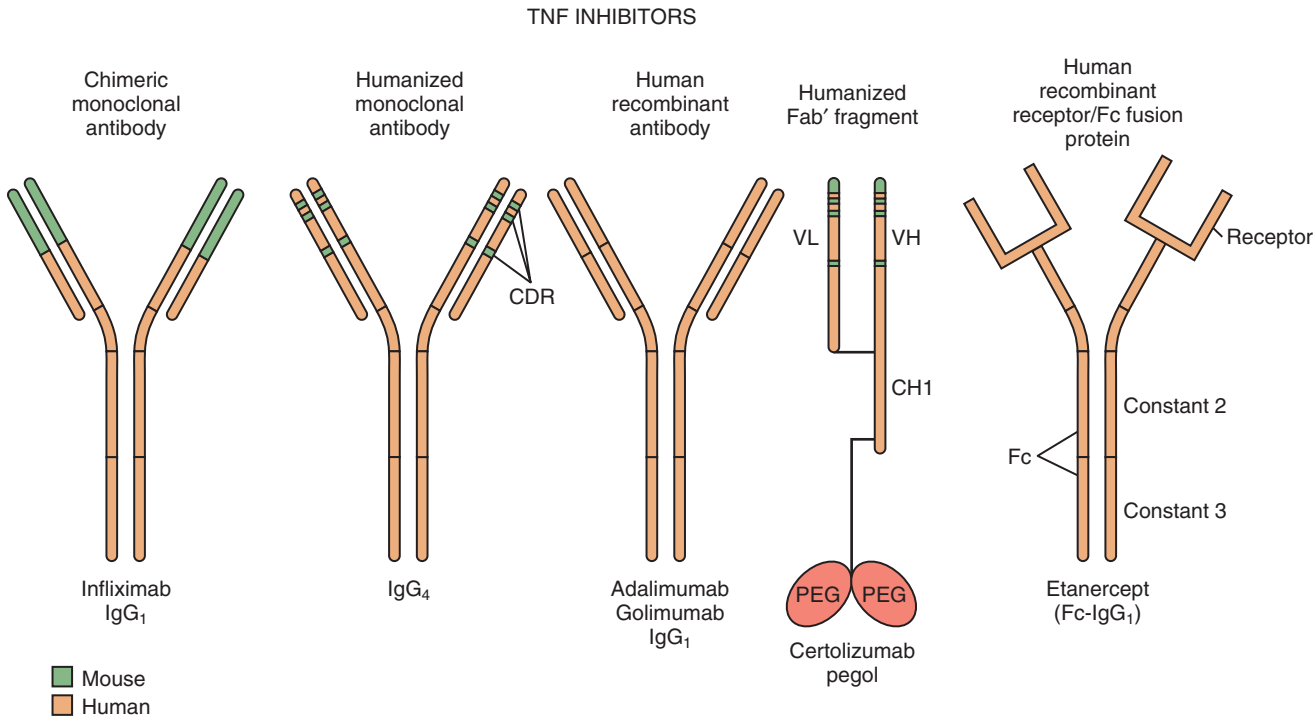

**Figure 63-1** Structures of infliximab, etanercept, adalimumab, golimumab, and certolizumab pegol. CDR, Complementarity-determining region; CH1, complement fixation; Fc, fragment crystallizable; FDA, U.S. Food and Drug Administration; PEG, polyethylene glycol; TNF, tumor necrosis factor; VH, variable heavy; VL, variable light.

### Pharmacokinetics

When administered subcutaneously, etanercept is absorbed slowly, reaching a mean Cmax approximately 50 hours after a single 25 mg dose. The Ig structure affords a half-life of 3 to 4.8 days. The volume of distribution suggests predominantly intravascular distribution.[12] The route of clearance from the circulation is unclear, although it is presumed to be mediated through Fc binding by the reticuloendothelial system. Different from what has been seen with anti-TNF monoclonal antibodies, concomitant use of MTX does not appear to alter the pK of etanercept.

### Drug Dose

Etanercept is administered by subcutaneous injection in doses of 25 mg twice weekly or 50 mg once weekly in RA, psoriatic arthritis (PsA), and ankylosing spondylitis (AS). Etanercept is approved for use as monotherapy or in combination with MTX. In skin psoriasis, a higher dose (50 mg twice weekly) is commonly used for the first 12 weeks of therapy. As is true of all available TNF inhibitors, in the clinic, etanercept has been used in combination with DMARDs other than MTX, for example, leflunomide, sulfasalazine, and others.

## Adalimumab

### Structure

Adalimumab is a human anti-TNF $IgG_1\kappa$ monoclonal antibody generated through repertoire cloning. Adalimumab neutralizes the biologic activity of TNF by binding with high affinity to the soluble and transmembrane forms of TNF and inhibiting the binding of TNF with its receptors (see Figure 63-1).

### Pharmacokinetics

The peak serum adalimumab concentration and the area under the curve increase linearly with doses in the range of 0.5 to 10 mg/kg. Adalimumab appears to have a low clearance and distributes mainly in the vascular compartment. Its elimination half-life is comparable with that of native $IgG_1$ (10 to 13.6 days). Concomitant use of MTX results in an approximate increase in the area under the curve of adalimumab of 25% to 30%.

### Drug Dose

The recommended dosing for adalimumab in RA, PsA, and ankylosing spondylitis is 40 mg subcutaneously every other week. In patients who do not achieve an optimal response, it is possible to increase the dosing frequency to weekly. Adalimumab is approved for use as monotherapy or in combination with MTX. In the clinic, it has been used in combination with a number of DMARDs other than MTX.

## Golimumab

### Structure

Golimumab is a human $IgG_1\kappa$ monoclonal antibody specific for human TNF. Golimumab was created by using

genetically engineered mice immunized with human TNF, resulting in an antibody with human-derived antibody variable and constant regions (see Figure 63-1).

### Pharmacokinetics

Following subcutaneous administration of golimumab to healthy patients and patients with RA, the median time to reach time to peak concentration (Tmax) ranged from 2 to 6 days. Golimumab exhibited dose-proportional pharmacokinetics in patients with active RA over the dose range of 0.1 to 10.0 mg/kg following a single IV dose. The volume distribution for golimumab indicates that golimumab is distributed primarily in the circulatory system with limited extravascular distribution. Median terminal half-life values were estimated to be approximately 2 weeks in healthy patients and patients with RA, PsA, or AS. When golimumab, 50 mg, was administered subcutaneously to patients with RA, PsA, or AS every 4 weeks, serum concentrations appeared to reach steady state by week 12. With concomitant use of MTX, treatment with golimumab every 4 weeks resulted in a mean steady-state trough serum concentration of approximately 0.4 to 0.8 μg/mL in patients with RA, PsA, or AS. Concomitant MTX usage resulted in higher mean steady-state trough concentrations of golimumab in patients with RA, PsA, or AS (52%, 36%, and 21%, respectively), compared with those treated with golimumab alone.[13]

### Drug Dose

Golimumab is administered by subcutaneous injection, 50 mg once a month, in patients with RA, PsA, and AS.

## Certolizumab Pegol

### Structure

Certolizumab pegol is a Fab fragment of a recombinant, humanized anti-TNF monoclonal antibody that has been fused to a 40 kDa PEG moiety. The Fab fragment is composed of a light chain with 214 amino acids and a heavy chain with 229 amino acids. Given this structure, certolizumab is not able to cause Fc-mediated activities complement-dependent or antibody-dependent cytotoxicity as seen with full monoclonal antibodies (see Figure 63-1).

### Pharmacokinetics

Single IV and subcutaneous doses of certolizumab pegol have predictable dose-related plasma concentrations with a linear relationship between the dose administered and the Cmax. A mean Cmax of approximately 43 to 49 μg/mL occurred at week 5 in patients with RA at the recommended dose regimen. Following subcutaneous administration, peak plasma concentrations of certolizumab pegol were attained between 54 and 171 hours postinjection. PEGylation, attachment of polyethylene glycol to Fab, delays the metabolism and elimination of these entities from the circulation by a variety of mechanisms, including renal clearance, proteolysis, and immunogenicity. The terminal elimination phase half-life was approximately 14 days for all doses tested.

### Drug Dose

The recommended dose of certolizumab pegol is 400 mg initially and at weeks 2 and 4, followed by 200 mg every other week. For maintenance dosing, certolizumab pegol 400 mg every 4 weeks can be considered. A 400 mg dose is given as two subcutaneous injections of 200 mg at separate sites in the thigh or abdomen.

### Efficacy of Tumor Necrosis Factor Inhibitors

**Rheumatoid Arthritis.** Infliximab, etanercept, and adalimumab were the first TNF inhibitors approved in many countries worldwide to treat RA. Initial studies demonstrated the efficacy and tolerability of various doses of TNF inhibitors and also established the optimal doses.[14–21] Concurrent therapy with MTX, even at a relatively low dose of 7.5 mg/wk, enhances the clinical response to all agents, and for infliximab and adalimumab, concomitant MTX decreases immunogenicity.[11] Almost all subsequent studies with TNF inhibitor drugs in RA have used such combination therapy.

Earlier trials demonstrated the efficacy and tolerability of infliximab, etanercept, and adalimumab in patients with long-standing, refractory, active disease despite MTX. All three agents have undergone extensive clinical trials that have shown superior efficacy compared with MTX alone as assessed by American College of Rheumatology (ACR) criteria.[19–25] In addition to achieving substantial efficacy, the use of TNF inhibitors was associated with significant improvement in patient's functional status and quality of life.[12,22,25] Perhaps most remarkably, patients receiving TNF inhibitors had a dramatic reduction in the progression of joint damage as assessed by radiographic change scores.[17,22,26]

Following the success achieved in patients with long-standing RA, this therapy was tested in patients with early RA (<3 years' duration). In the Active-Controlled Study of Patients Receiving Infliximab for the Treatment of Rheumatoid Arthritis of Early Onset (ASPIRE) trial, significant improvement in disease activity was noted in patients treated with infliximab plus MTX in comparison with MTX alone, at 54 weeks. In addition, although a significant increase in radiologic destruction was observed in patients treated only with MTX, a reduction in disease progression was observed in the infliximab plus MTX groups.[27] A detailed subanalysis of data from the Anti-TNF Therapy in RA with Concomitant Therapy (ATTRACT) study demonstrated that a significant radiographic benefit was achieved with infliximab plus MTX treatment even among patients who experienced no improvement in signs and symptoms of disease. This finding suggests that there may be an uncoupling among various outcomes, and that treatment with TNF inhibitors might lead to disease-modifying activity even in the absence of a clinical response.[28] Similar to infliximab, etanercept and adalimumab were effective in decreasing signs and symptoms of patients with early-stage RA and decreasing disease activity and the rate of radiographic progression. In long-term, open-label follow-up studies of patients from the clinical trials, responses to etanercept therapy have been sustained during a number of years, with some patients having received more than a

decade of treatment.[19] In the PREMIER trial, significantly less radiographic progression was observed among patients in the adalimumab plus MTX group at both 1 year and 2 years in comparison with the adalimumab or MTX-alone groups, although progression was less with adalimumab monotherapy than with MTX monotherapy.[29] Because this study was the first to include all three possible treatment arms (TNF inhibitor, MTX, and TNF inhibitor plus MTX), the study definitively established that combination therapy with MTX and TNF inhibitor achieves the best outcomes in patients with early-stage RA. Although TNF inhibitor monotherapy was superior to MTX alone in terms of radiographic progression, clinical efficacy was comparable; however, each of these was substantially less effective than the combination.

In the years after these studies, golimumab and certolizumab were approved for treatment of RA. In the GO-FORWARD study, patients with active RA despite treatment with a stable dose of MTX who had not been previously treated with a biologic TNF inhibitor were randomly assigned to receive golimumab, 50 mg, plus MTX; golimumab, 100 mg, plus MTX; or golimumab, 100 mg, monotherapy every 4 weeks. All golimumab regimens were significantly more effective at reducing signs and symptoms and in improving physical function.[30] Patients who were previously treated with one or more doses of TNF inhibitor without a serious adverse reaction were enrolled in the GO-AFTER study. Greater efficacy measured by ACR20 and Disease Activity Score (DAS) 28 was observed in patients who received golimumab 50 mg plus MTX with patients who received MTX alone.[31] Patients with active RA who were MTX naïve and had not been previously treated with TNF inhibitor were randomly assigned to treatment with MTX alone; golimumab, 50 mg, plus MTX; golimumab, 100 mg, plus MTX; or golimumab, 100 mg, alone in the GO-BEFORE study. Golimumab plus MTX led to significant improvement in ACR responses.[32] An MRI substudy of the GO-BEFORE and GO-FORWARD trials demonstrated that patients who received golimumab plus MTX had improvements in inflammation (synovitis and osteitis) greater than patients with received MTX only, as early as week 12 and continuing through week 24.[33]

In the Rheumatoid Arthritis Prevention of Structural Damage (RAPID)-I and RAPID-II studies, lyophilized liquid preparations of certolizumab were evaluated. Patients were randomly assigned to receive loading doses of 400 mg of certolizumab pegol or placebo at weeks 0, 2, and 4, followed by 200 mg of certolizumab pegol, 400 mg certolizumab pegol, or placebo every other week in combination with MTX. Certolizumab pegol–treated groups showed rapid and sustained improvement in clinical disease activity, starting from week 1 and continuing through week 52. Mean radiologic progression was significantly reduced in the certolizumab-treated groups versus MTX alone.[34–36] Sustainability of improvements in RA signs and symptoms and inhibition of joint damage progression, as well as tolerability of certolizumab pegol plus MTX, were evaluated in the RAPID-II open-label extension study.[37] In a broader group of RA patients with inadequate response to more than one DMARD, including prior TNF inhibitor exposure, addition of certolizumab pegol to the regimen resulted in rapid clinical response measured with ACR20 response rates and DAS28 scores, and improved function measured with Health Assessment Questionnaire (HAQ) scores.[38]

**Psoriatic Arthritis (PsA).** The impressive efficacy of TNF inhibitors in RA led to studies of these agents in patients with PsA. Similar to RA trials, multiple randomized clinical trials with five TNF inhibitors demonstrated significant improvement in disease activity, quality of life, function, and slowing of disease progress as evidenced by radiographic changes. In addition, disease-specific clinical findings such as skin and nail psoriasis, enthesitis, and dactylitis have also been shown to improve significantly.

In the Infliximab Multinational Psoriatic Arthritis Controlled Trial 1 (IMPACT 1), the response to infliximab therapy defined by ACR20 and Psoriatic Arthritis Response Criteria was evident as early as week 2, and improvement continued through week 50. Significant improvements were also seen in skin psoriasis and in dactylitis and enthesitis assessments.[39] In the phase III (IMPACT 2) trial, clinical improvement was seen very early in the infliximab-treated groups, and the response was maintained with continued treatment through the end of the study. In the same group of patients, infliximab inhibited radiographic progression and quality of life.[40,41]

In the initial double-blind, placebo-controlled clinical trial with etanercept, substantial improvements were observed in PsA and ACR20 response criteria.[42] In a subsequent study, 59% of etanercept-treated patients met the ACR20 criteria, compared with 15% of the placebo group. During the open-label extension, patients continuing with etanercept treatment maintained or improved their clinical responses and showed inhibition of radiographic progression.[43]

Similar success was achieved in clinical trials with adalimumab. A significantly higher percentage of patients from the adalimumab-treated group reached ACR20, ACR50, and ACR70 response criteria compared with the placebo group.[44] Moreover, the rate of radiographic damage progression was significantly attenuated with adalimumab. As was true in studies of the other TNF inhibitors in PsA, MTX was permitted but not required for enrollment in the study. With this design, there seemed to be no difference in efficacy or toxicity between the combination of MTX plus adalimumab and adalimumab monotherapy. In addition to improvements in various articular manifestations, dramatic improvements were noted in skin psoriasis with adalimumab treatment.

In the GO-REVEAL study, patients with active PsA despite nonsteroidal anti-inflammatory drug (NSAID) or DMARD therapy who had not been previously treated with TNF inhibitor were randomly assigned to receive golimumab, 50 mg or 100 mg, with or without MTX every 4 weeks. Fifty-one percent of patients who received golimumab reached ACR20 response at week 14 in comparison with 9% of patients who received only MTX. Significant improvements in enthesitis and HAQ scores were seen in patients treated with golimumab.[45] Long-term radiologic outcome was assessed by using the van der Heijde–Sharp (vdH-S) method modified for PsA and showed minimal evidence of radiographic disease progression through week 104.[46]

In the RAPID-PsA study, patients with and without prior TNF inhibitor exposure were included. Active and

progressive PsA patients received a loading dose of certolizumab 400 mg, followed by either 200 mg every other week, 400 mg every 4 weeks, or placebo every other week. ACR20 results showed that certolizumab rapidly improved signs and symptoms, with patient response observed as early as the first week of treatment for some patients. ACR20, -50, -70 response rates were higher for each certolizumab group relative to the placebo group. Patients treated with certolizumab 200 mg every other week demonstrated greater reduction in modified total Sharp score (mTSS) compared with placebo-treated patients.[47] Statistically significant improvement in physical function from baseline measured by Health Assessment Questionnaire Disability Index (HAQ-DI) was reported in comparison with the placebo group. Sustained improvements were observed in enthesitis and dactylitis as well.

**Ankylosing Spondylitis.** Five TNF inhibitors have been widely studied in AS; all showed remarkable similarity in their efficacy in relieving symptoms of AS. Studies have shown that TNF inhibitors improve health-related quality of life, patient-reported outcomes, anemia, C-reactive protein (CRP) levels, and sleep quality in patients with AS. TNF inhibitors control inflammation in the spine, as measured by various MRI sequences. Interestingly, despite all of these notable effects, TNF inhibitor therapy does not attenuate radiographic progression in AS. There are several potential reasons for this. Unlike RA, radiographic outcomes in AS measure reflect mainly osteoblastic activity with syndesmophyte formation; it is possible this is affected less by TNF inhibition. Also, the study durations may not have been long enough to show an effect. In that regard, longer-term treatment, that is longer than 4 years, with TNF inhibitors might reduce the rate of new bone formation in patients with AS.[48]

In the initial double-blind, placebo-controlled, randomized trial with infliximab, disease activity in patients taking infliximab measured by the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), functional ability measured by the Bath Ankylosing Spondylitis Functional Index (BASFI), and mobility of the spine measured by the Bath Ankylosing Spondylitis Metrology Index (BASMI) significantly improved compared with the placebo group.[49] A significantly higher percentage achieved 50% or greater improvement in the BASDAI, and 25% of patients who completed the trial were in partial remission, according to the Assessment in Ankylosing Spondylitis (ASAS) criteria among patients who continued to receive infliximab every 6 weeks until week 102.[50] In addition, the incidence of enthesitis and, importantly, anterior uveitis significantly decreased during the third year of treatment in comparison with baseline.[51] To analyze the time to relapse after discontinuation of anti-TNF therapy, infliximab was stopped. Interestingly, most patients had a flare up, with a mean time to relapse of 17.5 weeks after cessation of infliximab infusions. Importantly, re-treatment with infliximab was safe and resulted in clinical improvement in all patients to a state similar to that achieved previously.[52] In another trial, 2 years of continuous infliximab therapy resulted in persistent improvement in spinal inflammation determined by both T1-weighted gadolinium-enhanced and by short tau inversion recovery MRI sequences in all AS patients.[53] Of note, disease activity parameters did not directly correlate with MRI results.

Similarly positive results were observed with etanercept therapy in patients with AS. In a double-blind, placebo-controlled, randomized clinical trial, significant improvement in clinical response (defined by ASAS20) was demonstrated in etanercept-treated patients throughout the 24-week study.[54] Sustained clinical response was maintained in the open-label extension of this study throughout 96 weeks of treatment.[55] Health-related quality-of-life assessments also significantly improved with etanercept.[56] The extent of clinical response was similar in subsequent clinical trials. Improvement measured by ASAS20 was noted as early as 2 weeks after etanercept therapy was started, and the response was maintained throughout the trial. In a subsequent multicenter trial, significant improvements in BASDAI, BASFI, and BASMI scores were achieved initially in the etanercept-treated group, and later in all patients after the placebo group received etanercept as well. Relapses occurred at a mean of 6 weeks after cessation of etanercept.[57] Re-administration of etanercept led to similar results in the same group of patients. Most patients were able to completely discontinue NSAIDs. Spinal inflammation on MRI decreased by 54% in the etanercept group but worsened by 13% in the placebo group after 12 weeks of therapy. After switching to etanercept, placebo patients experienced a similar improvement in spinal inflammation.[58] Finally, it was demonstrated that continuous treatment with etanercept for 24 weeks reduced active spinal changes by 69%, as measured by different MRI sequences.[59]

In an adalimumab trial that evaluated long-term efficacy and safety in AS (known as the *ATLAS* trial), patients received either 40 mg of adalimumab or placebo every other week for 24 weeks. The number of participants who met ASAS partial remission criteria was significantly higher in the adalimumab group at weeks 12 and 24 in comparison with the placebo group. The number of participants who met ASAS 5/6 criteria (20% improvement in five of six domains, without 20% worsening in the sixth domain) at weeks 12 and 24 was also significantly higher in the adalimumab-treated group.[60] Significant improvement in health-related quality of life was reported in this group of patients.[61] The efficacy of adalimumab was demonstrated not only by improved clinical indices but also by sacroiliac and spinal inflammation assessed by MRI.[62]

The efficacy of golimumab in AS was evaluated in the GO-RAISE study.[63] Patients with active AS, according to modified New York criteria, were randomly assigned to receive placebo or golimumab every 4 weeks. Patients were allowed to be on stable doses of sulfasalazine, hydroxychloroquine, low-dose corticosteroids, or NSAIDs during the trial. The use of other DMARDs was prohibited. At weeks 14 and 24, patients taking golimumab 50 mg, once a month demonstrated significant ASAS20 and ASAS40 responses (56% and 44%, respectively) versus the placebo group (23% and 15%, respectively).[63] Golimumab significantly reduced MRI-detected spinal inflammation of AS; improvements were correlated with improvement in ASDAS and CRP levels.

Following the new classification of AS in 2011, certolizumab was evaluated in patients with axial spondyloarthritis

(axSpA), including patients with AS and nonradiographic axSpA (nraxSpA). In the RAPID-axSpA study, certolizumab reduced the signs and symptoms of axSpA. ASA20 response rates were significantly higher in patients treated with certolizumab 200 mg every 2 weeks and 400 mg every 4 weeks. The combined certolizumab arms of the study showed significant differences in change from baseline versus placebo in BASFI, BASDAI, and BASMI. Improvement was observed as early as week 1. Similar improvements were reported with certolizumab versus placebo in both AS and nraxSpA subpopulations. In addition, 12 weeks of treatment with certolizumab reduced inflammation in sacroiliac joints and spine in patients with axSpA.[64]

## Mechanism of Action of TNF Inhibitors

Several potential mechanisms of action might explain the efficacy of TNF inhibitors in RA and other conditions (Table 63-1). However, the exact relationship between any particular mechanism and specific aspects of clinical efficacy remains to be demonstrated. Downregulation of local and systemic pro-inflammatory cytokine production and reduction of lymphocyte activation and migration into the joint may be the most relevant mechanisms; for example, serum levels of IL-6 and IL-1 are significantly reduced after administration of anti-TNF monoclonal antibody.[65] The reduction in TNF and the consequent reduction in IL-1 would be expected to reduce the synthesis of matrix metalloproteinase (MMP) and the production of other degradative enzymes. Serial studies have shown that there is in fact a marked reduction in pro–MMP-3 and pro–MMP-1 after anti-TNF therapy.[13,66,67]

As noted, anti-TNF therapy is also associated with a reduction of lymphocyte migration into the joints of patients with RA. With radiolabeled granulocytes, it has been demonstrated that anti-TNF monoclonal antibody significantly reduces cell movement into the affected joints.[68] In addition, post-treatment synovial biopsies show reduced cellular infiltrates, with fewer T cells and macrophages present.[69]

**TABLE 63-1** Potential Mechanisms of Action of Tumor Necrosis Factor Inhibitors

| Modulate HLA-DR expression |
| Increase apoptosis (?) |

HLA-DR, Human leukocyte antigen DR; IL, interleukin; GM-CSF, granulocyte-macrophage colony-stimulating factor; MMPs, matrix metalloproteinases; Th, T helper.

These effects are thought to be secondary to a reduction in the expression of endothelial adhesion molecules in the synovial tissue. Treatment with anti-TNF monoclonal antibody results in a dose-dependent decrease in soluble forms of intercellular adhesion molecule-1 (ICAM-1) and E-selectin (CD62E).[68] Changes in soluble E-selectin, soluble ICAM-1, and circulating lymphocytes with anti-TNF therapy correlate with clinical outcomes. Vascular endothelial growth factor (VEGF) is a potent endothelial cell–specific angiogenic factor. It is produced in the synovium and is an important regulator of neovascularization in the pannus. After anti-TNF therapy, VEGF serum levels are reduced in patients with RA. This decrease correlates significantly with the clinical benefit observed in these patients.[70] Because angiogenesis is a prominent feature of rheumatoid synovium, the relationship between inflammation and angiogenesis has been investigated. Computerized image analysis of endothelium for multiple markers of endothelium (e.g., von Willebrand factor, CD31) and neovasculature ($\alpha v\beta 3$) has shown reduced vascularity after anti-TNF therapy. A number of other potential mechanisms of action are suggested to be operative for TNF inhibitors (see Table 63-1), although debate on these aspects is ongoing.

## Other Considerations

### Treatment in Other Autoimmune Conditions

The role of TNF inhibitors in the treatment of Crohn's disease, juvenile idiopathic arthritis, and psoriasis has been clearly defined. Based on promising results in various immune conditions, these agents have been used in a variety of other disorders, including idiopathic and spondyloarthropathy-related anterior uveitis, sarcoidosis, Sjögren's syndrome, Behçet's disease, inflammatory myopathies, and various types of vasculitis. Although a number of case reports or small, uncontrolled clinical trials have reported on these conditions, there is a paucity of conclusive data from controlled trials. Perhaps the most notable clinical response has been observed in the treatment of anterior uveitis, especially with anti-TNF monoclonal antibody constructs.[71] On occasion, promising results in uncontrolled trials have been disproved in controlled trials. This was observed in a placebo-controlled trial of etanercept given in addition to standard therapy for remission induction and maintenance in patients with granulomatosis with polyangiitis. Despite promising anecdotal evidence, the addition of the TNF inhibitor not only failed to cause any clinical improvement in the patient but also resulted in greater risk of solid malignancies beyond that observed with cyclophosphamide alone.[72]

Despite evidence that anti-TNF agents can result in the development of certain autoantibodies and even lupus-like syndromes, the safety and efficacy of anti-TNF agents have been assessed in a small group of patients with systemic lupus erythematosus (SLE). Patients with joint involvement experienced remission of arthritis, and a significant reduction in the level of proteinuria occurred with infliximab. In this small study, TNF inhibitor therapy did not lead to adverse events suggestive of an increase in SLE activity; however, as might have been expected, autoantibodies to double-stranded DNA and cardiolipin did increase.[73]

### Cardiovascular Risk and Lipid Profile

Cardiovascular morbidity and mortality appear to be increased in autoimmune conditions. This may be related both to increased prevalence of traditional risk factors for cardiovascular disease and to uncontrolled systemic inflammation, which appears to predispose independently to accelerated progression of atherosclerosis. Treatment with TNF inhibitors appears to be associated with overall improvement in cardiovascular disease risk, related to beneficial effects on lipid parameters and to control of systemic inflammation.[74] Long-term investigations are needed to define the possible beneficial effects of TNF inhibitors on overall and cardiovascular survival in patients with autoimmune disease.

### Monitoring

All patients must be evaluated for active and inactive (latent) tuberculosis infection before initiation of therapy. Appropriate screening tests (e.g., tuberculin skin test, ex vivo testing for tuberculosis, chest radiograph) should be performed on all patients. Use of TNF inhibitor therapy may increase the risk of reactivation of hepatitis B virus (HBV) among patients who are chronic carriers of HBV. Therefore evaluating patients for HBV before starting TNF inhibitor therapy is recommended. No other specific laboratory monitoring is currently required by regulatory agencies during therapy with TNF inhibitors. Nevertheless, because of the rare occurrence of myelosuppression and concern about the risk of infection, clinicians typically assess the complete blood count intermittently during therapy. Assiduous monitoring of patients for any sign or symptom of infection, demyelinating disease, and malignancy is requisite during treatment with all TNF inhibitors. Repeat testing at regular intervals (e.g., annually) for exposure to tuberculosis has been recommended by some regulatory authorities.

### Pregnancy and Breastfeeding

Developmental toxicity studies in rats, rabbits, and mice have not revealed any maternal toxicity, embryo toxicity, or teratogenicity associated with TNF inhibition. Minimal human pregnancy information has been published for these medications, and most data consist of isolated case reports, retrospective surveys, and uncontrolled studies. As the number of patients treated with TNF inhibitors increases, a growing number of pregnancies will be reported among them.[75] Outcome data based on anecdotal observations of small numbers of pregnant women treated with infliximab, etanercept, and adalimumab reveal that the relative rates of live births, miscarriages, and therapeutic terminations were comparable with rates in a national cohort of age-matched healthy women. TNF inhibitors are classified as U.S. Food and Drug Administration (FDA) Pregnancy Category B (animal reproduction studies have failed to demonstrate a risk to the fetus, and no adequate and well-controlled studies have been performed in pregnant women). The use of anti-TNF agents in pregnancy is recommended only if such treatment is clearly needed. If TNF inhibitors are used during pregnancy, transfer to the fetus is possible, and monitoring might be considered on that basis. Because it is not currently known whether TNF blockers are excreted in human milk, or whether they are absorbed systemically after ingestion, it is recommended that TNF blockers not be used by nursing mothers.

### Vaccinations

It is preferred to have all recommended vaccinations brought up to date in patients before initiating treatment with TNF inhibitors. Because data on the response to live vaccinations or the secondary transmission of infection by live vaccinations in patients receiving TNF inhibitors are insufficient, concurrent administration of live vaccines with TNF inhibitors is not recommended.

### Toxicity

In clinical trials, etanercept, infliximab, adalimumab, golimumab, and certolizumab pegol have generally been well tolerated.[21,22,24–32,36] Longer-term follow-up of patients initially enrolled in clinical trials has provided additional safety data for these agents. However, TNF plays a key role not only in the pathogenesis of autoimmune disease but also in normal immune homeostasis. Therefore a number of safety considerations, including the potential risk of infection and malignancy, are germane to the optimal clinical use of these agents.[76]

Additional information concerning adverse effects associated with these agents has been obtained through pharmacovigilance. Adverse events related to the use of TNF inhibitors can be grouped into those that are agent related and those that are target related (Table 63-2)[77] Injection site and infusion reactions and immunogenicity and their sequelae vary, depending on the particular agent. A potentially increased predisposition to infection, development of malignancy, and induction of autoimmune disorders and an association with demyelinating disorders, myelosuppression, and worse outcomes with congestive heart failure might be

**TABLE 63-2** Adverse Effects Potentially Associated with Tumor Necrosis Factor Inhibitors

| |
|---|
| **Target-Related** |
| Infections (including serious infections) |
| Opportunistic infections (e.g., tuberculosis) |
| Malignancies (skin cancer, lymphoma [?]) |
| Demyelinating conditions |
| Hematologic abnormalities |
| Congestive heart failure |
| Autoantibodies (anti-nuclear antibody, anti–double-stranded DNA) |
| Hepatotoxicity |
| Dermatologic reactions |
| Lupus-like syndromes |
| **Agent-Related** |
| Administration reactions |
| Immunogenicity |

considered target-related adverse events. Thus any clinically effective TNF inhibitor might be expected to be associated with such adverse events, although the relative risk among different agents may vary, depending on dose and other factors.

**Infusion and Injection Site Reactions.** Infliximab has been associated with infusion reactions, the most common of which are headache (20%) and nausea (15%). These are rarely severe, are usually transient, and typically can be controlled by slowing the rate of infusion or by treating with acetaminophen or antihistamines.[22] With etanercept, adalimumab, golimumab, and certolizumab pegol, cutaneous reactions at injection sites represent the most frequent administration-related side effect; however, they rarely lead to discontinuation of therapy[25,31] Injection site reactions typically consist of erythematous or urticarial lesions. Although they can arise at sites of previous injections, these reactions seem to be limited to the skin and are not associated with other or systemic features of immediate hypersensitivity. Reactions typically occur close to treatment initiation and abate over time, even with continued dosing.

**Antigenicity.** As is true for any therapeutic agent (especially large protein molecules, some of which contain foreign sequences), antibodies to anti-TNF agents can develop. Although the clinical relevance of these antibodies is presently unclear, they can diminish the half-life of the therapeutic agent and consequently decrease its efficacy. Antibodies to the drug develop in approximately 3% of etanercept-treated patients. In an early study, it was noted that antibodies to infliximab developed in 53%, 21%, and 7% of patients who were receiving 10, 3, and 1 mg/kg infliximab, respectively,[12] RA trials of infliximab with or without concomitant MTX treatment revealed that immunogenicity was decreased by concomitant MTX, perhaps in part because of the increase in the half-life of infliximab associated with MTX use. A multicenter trial of infliximab therapy in Crohn's disease demonstrated that induction of these anti-infliximab antibodies might contribute to hypersensitivity reactions in some patients. Antibodies to adalimumab, golimumab, and certolizumab pegol developed in approximately 4% to 12% of patients; this rate was reduced to 1% with concurrent MTX treatment.[31–33,46,63] Although it is believed that there is a trend toward higher clearance of TNF inhibitors in the presence of antibodies to the construct, routine testing for antibodies to TNF inhibitors is not widely available, nor is it currently recommended.

**Infection.** Given that TNF is a key mediator of inflammation, a major concern surrounding the use of TNF inhibitors is their potential to increase the risk of infection. Although inhibition of TNF in animals does not appear to increase their risk for infection with most pathogens, it does interfere with the ability to mount an inflammatory response against intra-cellular organisms. In experimental models, TNF blockade impaired resistance to infection with mycobacteria, *Pneumocystis carinii*, fungi, *Listeria monocytogenes*, and *Legionella*. In patients with RA, infection with these types of opportunistic organisms has been observed. However, confounding the attribution of infection to any therapeutic agent is the fact that infections occur more frequently and are important contributors to the accelerated morbidity of RA patients compared with the normal population. It is difficult to determine how much of this susceptibility relates to the disease itself and how much it is caused by the effects of immunomodulatory drugs (e.g., steroids and DMARDs). The subset of RA patients with great susceptibility to infection (i.e., those with severe, active disease) is also the subset most commonly enrolled in trials of TNF inhibitors. This is the group of patients for whom these agents have the greatest clinical utility.

In RA trials with TNF inhibitors, a number of infections have occurred. In general, the most frequent infections have been those that occur most commonly among all persons, such as upper and lower respiratory tract infections and urinary tract infections. In most studies, a slightly greater propensity to infection was seen in patients receiving TNF inhibitors; however, this trend is common in most studies of effective therapies for RA. The incidence of serious infection, defined as infection requiring hospitalization or treatment with parenteral antibiotics, among RA patients treated with TNF inhibitors was similar to that of the control groups in individual studies. The incidence also approximated that noted among RA patients before the anti-TNF era[78] In certain subgroups, such as patients with early RA, the overall incidence of infection was less than in patients with more long-standing disease, and infections and serious infections were comparable among TNF inhibitor–treated patients and controls.

It is worth noting, however, that several characteristics of clinical trials might affect investigators' ability to extrapolate their safety data to the clinic. In general, patients enrolled in clinical trials tend to be healthier and therefore less likely to develop adverse effects such as infection, compared with the general population of RA patients in the clinic. Therefore post-marketing data provide an important complement to safety data obtained from clinical trials. Also, clinical trials are powered to assess efficacy and therefore may not include sufficient numbers of patients to ascertain real but small differences in uncommon side effects. A systematic analysis that combined the results from nine clinical trials of TNF inhibitors has been performed.[79] This analysis found an increased risk of serious infection among patients receiving TNF inhibitors compared with controls (3.6% vs. 1.7%). However, a nonstandard definition of serious infection was used, and no attempt was made to control for the time of exposure, which was nearly always longer for patients receiving TNF inhibitors. In this same analysis, a nonsignificant trend toward a greater incidence of serious infection was observed with higher doses of TNF inhibitor. In one of the only clinical trials that had a primary outcome of safety, use of a high-dose TNF inhibitor was also associated with a greater incidence of serious infection compared with a lower dose; the lower dose was no different from placebo in this regard.

In post-marketing surveillance data, also known as *pharmacovigilance*, serious infections have certainly been observed among patients receiving TNF inhibitors[76] The relative impact of potentially confounding factors, such as comorbidities and concomitant medications on the rate of serious infection, remains incompletely defined. This important question has also been addressed by using registries of RA patients.[80,81] In a German registry, rates of infection and serious infection among 858 RA patients receiving treatment with TNF inhibitors were compared with those among

601 patients receiving only DMARDs.[81] The relative risk (RR) for infection (3.3 to 4.1) as well as serious infection (2.7 to 2.8) was significantly higher among patients receiving TNF inhibitors. However, these patients also had more severe and more active RA, thereby placing them at greater risk of infection. When the investigators used propensity scoring methods to control for severity of disease as a confounder, the RRs were reduced. The risk of infection decreased to 2.3 to 3.0, and that for serious infection became a nonsignificant trend of 2.1. In data from a British registry, 7644 RA patients treated with TNF inhibitors were compared with 1354 RA patients on DMARDs alone.[78] In this analysis, the crude rate of serious infection was higher among TNF inhibitor–treated patients (1.28; 95% confidence interval [CI], 0.94 to 1.76), although this did not reach statistical significance. Further, when the rates were adjusted for age, sex, severity of RA, use of corticosteroids, and comorbidity, no differences between the groups were noted (RR, 1.03; 95% CI, 0.68 to 1.57).

In summary, although treatment with TNF inhibitors can result in increased risk of infection and serious infection, other factors such as the severity of RA, the use of other medications such as corticosteroids, and the presence of comorbidities are important contributors to these outcomes. Clinicians must monitor patients closely for signs and symptoms of infection, and it is worth noting that TNF inhibitor therapy itself can mask the initial signs and symptoms of infection.

Opportunistic infections, particularly disseminated *Mycobacterium tuberculosis*, are of concern with the use of TNF inhibitors. Of note, more patients treated with TNF inhibitors have extrapulmonary and disseminated tuberculosis (TB), highlighting the specific role of TNF in controlling this infection. Rates of TB associated with the use of TNF antagonists are higher in geographic regions where TB is more prevalent in the general population. Most cases of TB observed in the early years after the introduction of TNF inhibitors arose within the first few months after initiation of therapy and were probably related to the reactivation of latent TB. Very few cases of TB were observed during clinical trials of the TNF inhibitors, highlighting the important role of pharmacovigilance in identifying safety signals with new therapies. For etanercept, no cases of TB occurred in clinical trials, but 38 cases of etanercept-associated TB were reported worldwide among an estimated 150,000 patients exposed through December 2002. For infliximab, 441 cases of TB were reported among approximately 500,000 initially exposed patients; only 6 cases of infliximab-related TB were reported from clinical trials. Ninety-seven percent of infliximab-related cases occurred within 7 months of treatment initiation, with a median time of onset of 12 weeks. The incidence of TB in clinical trials with adalimumab was greater in earlier clinical trials; this was related to lack of screening, the locations of the studies, and the higher doses used in early trials. The incidence dropped to 1% after adalimumab was reduced to its current dose, and after screening for latent TB infection was instituted before therapy (21 cases in 2400 patients).[82] The incidence of TB was even lower in golimumab and certolizumab pegol trials. The incidence of TB was 0.23 in golimumab clinical trials, and most cases occurred in countries with a high incidence rate of TB.[31–63] In studies with certolizumab pegol, 36 cases of TB occurred among 2367 exposed patients; these cases also occurred in countries with endemic rates of TB. This highlights the benefit of screening for and treating latent TB among patients being considered for TNF inhibitor therapy.[34–36] However, because treated patients may acquire new cases of TB, and because cases of latent TB may be missed because of false-negative screening tests, constant vigilance for TB is required during therapy with TNF inhibitors.

The impact of screening for latent TB in patients receiving anti-TNF agents has been assessed in a Spanish registry; the rate of development of active TB among RA patients treated with anti-TNF agents dropped by 83% with use of the recommended guideline. Current U.S. guidelines recommend purified protein derivative (PPD) skin testing and/or ex vivo testing for tuberculosis, as well as a chest radiograph, before anti-TNF therapy is initiated. If the PPD test is positive without evidence of active infection, treatment for latent TB with isoniazid is recommended. The recommended duration of therapy is 9 months. Recommendations concerning the timing of TNF inhibitor therapy and isoniazid prophylaxis for latent TB vary; however, concomitant initiation appears feasible.[20] During anti-TB treatment, alanine aminotransferase (ALT) monitoring is recommended, especially for those who chronically consume alcohol and/or who take potentially hepatotoxic drugs. Treatment should be adjusted according to local guidelines.

**Malignancy.** Anti-TNF drugs can theoretically affect the host defense against malignancy. To date, the occurrence of malignancies in clinical trials and long-term follow-up of RA patients from clinical trials do not appear to significantly exceed the rate that would be expected in this population. The overall rate of most malignancies in patients with RA is the same as in the normal population. However, risks of certain cancers, such as lymphoma and lung cancer appear to be increased in patients with RA. Although the actual reason is not known, the severity and activity as well as duration of the disease, and the use of immunomodulatory agents such as MTX, seem to play a role in the increased risk of lymphoma in RA patients.[83] Postmarketing analysis of the association between anti-TNF agents and lymphoma is inconclusive. In one population-based analysis, standardized incidence ratios of lymphoma among patients receiving anti-TNF therapies were somewhat higher than those among RA controls; however, this analysis did not adjust for baseline differences between patients.[83]

In a more recent analysis, in which adjustments were made for age, sex, and disease duration, no increased risk of lymphoma was identified among RA patients treated with anti-TNF agents compared with patients treated with other therapies. In clinical trials of anti-TNF monoclonal antibodies, malignancies, including lymphomas and skin cancers, were noted with treatment, but the extra duration of exposure to TNF inhibitors was not accounted for. Overall, TNF inhibitor therapy does not appear to be associated with a major increase in the risk of cancer. Still, this requires consideration for each individual, especially in certain situations, such as RA patients with a history of malignancy. No data from clinical trials address this because patients with cancers are excluded. Data from several

registries have suggested that no increase in risk of recurrent cancer may exist among such patients treated with TNF inhibitors, but more data are required.[84]

Although anti-TNF agents are used frequently in children, a possible increased risk of malignancies in children with autoimmune disorders, particularly in those receiving TNF inhibitors, has been pointed out by the Adverse Event Reporting System of the FDA. Forty-eight reports of malignancy were identified: 31 following infliximab use, 15 following etanercept use, and 2 following adalimumab use. Half of the malignancies were lymphomas, and most cases involved concomitant use of other immunosuppressants.[85] Given these uncertainties, caution is indicated when the use of anti-TNF agents is considered for patients with a history of malignancy or for those at high risk of malignancy for other reasons. Longer-term follow-up of larger numbers of patients will provide clinicians with a better idea of the safety of these agents in this regard.

**Autoimmune Disorders.** Antibodies to double-stranded DNA develop in approximately 10% to 15% of patients treated with any TNF inhibitor.[76] However, symptoms consistent with drug-induced lupus develop in few patients (0.2% to 0.4%). The mechanism and the significance of the development of antibodies are uncertain, although this adverse effect seems relatively specific for TNF inhibitors and is not noted with other biologic agents. Of note, life-threatening lupus involvement (e.g., nephritis, central nervous system lupus) generally does not develop in patients with TNF inhibitor–related lupus, and the diversity of other autoantibodies characteristic of idiopathic SLE (e.g., anti-Sm/RNP, anti-Ro/La, anti-Scl70) rarely develops in these patients. Anti-cardiolipin antibodies have reportedly developed in a few patients, but they are mostly asymptomatic. Among those few patients in whom lupus-like symptoms developed while they were on TNF inhibition therapy, improvement was seen upon discontinuation of therapy. Although the rare occurrence of autoimmune disorders has not dissuaded most clinicians from using TNF inhibitors in patients with RA, some remain cautious about using these drugs in patients with a history of SLE.

**Demyelinating Syndromes.** Several cases of multiple sclerosis (MS) or peripheral demyelinating disease have been reported with anti-TNF therapy in patients with RA, PsA, and Crohn's disease. In addition, two studies of TNF inhibitors in MS patients showed worsening of MS-related symptoms and exacerbations in the treated group.[86] Although some evidence suggests that the incidence of MS may be increased in patients with RA, the association between anti-TNF therapy and MS remains unclear. The risk for a demyelinating disease is very small; however, many clinicians withhold anti-TNF therapy in patients with a history of demyelinating diseases and in those who show signs and symptoms of such disease during anti-TNF therapy.

**Congestive Heart Failure.** Data suggest that TNF may play a role in the pathogenesis of congestive heart failure (CHF), and inhibition of TNF was highly effective in animal models of ischemic cardiomyopathy. However, in trials of TNF inhibitors in patients with stable but severe (class III or IV) CHF, no clinical benefit was observed, and in some treatment arms, higher incidences of mortality and hospitalization for worsening of CHF were reported. Thus TNF inhibition has been largely abandoned as a therapeutic approach in patients with CHF. In patients with RA, treatment with TNF inhibitors does not appear to result in an increased incidence of CHF.[87] In fact, TNF inhibitor therapy may actually improve mortality associated with heart disease and overall mortality in RA patients.

## INTERLEUKIN-1

Members of the IL-1 family include IL-1α, IL-1β, and the naturally occurring IL-1 receptor antagonist (IL-1Ra). Specific cellular proteases process IL-1α and IL-1β to their 17 kDa mature forms. Pro–IL-1α precursor is active intracellularly. However, pro–IL-1β is not active before cleavage with IL-1β–converting enzyme. After cleavage, it is secreted and is fully functional. IL-1Ra is a naturally occurring antagonist protein with amino acid sequence homology to IL-1α and IL-1β. Multiple forms of this protein exist. One is secreted and functions as a competitive inhibitor of IL-1α and IL-1β, binding to the same counter-receptor but transducing no signal. The IL-1 polypeptides bind to two cell surface receptors: type I (IL-1RI) and type II (IL-1RII). IL-1RI is found on most cell types, whereas IL-1RII occurs mainly on the surface of neutrophils, monocytes, B cells, and bone marrow progenitor cells. When IL-1 binds to IL-1RI, the signal transduction is mediated through the association of a second receptor unit, IL-1R accessory protein. The three members of the IL-1 family bind to IL-1RI with similar affinities. Binding of IL-1 to IL-1RII does not lead to signal transduction. IL-1RII acts like a decoy receptor and a competitive inhibitor. Soluble forms of IL-1RII inhibit IL-1 activity by competing with IL-1RI for IL-1 binding. IL-18 is another member of the IL-1 family of inflammatory cytokines. It is now recognized as an important regulator of innate and acquired immune responses. IL-18 is expressed at sites of chronic inflammation, in autoimmune diseases, in a variety of cancers, and in the context of numerous infectious diseases. IL-18 likely plays a role in RA, and strategies to block IL-18 activity are underway in clinical trials.

As with TNF, IL-1 is one of the key mediators of the inflammatory response. Studies in animal models of arthritis have demonstrated the therapeutic potential of IL-1 blockade. IL-1β gene knockout mice show markedly reduced levels of inflammation following immunization with type II collagen. The use of genetically modified mice has helped to confirm the physiologic significance of IL-1Ra. Deletion of this gene in mice results in the spontaneous development of arthritis.

### Anakinra

#### Structure and Mechanism of Action

Anakinra is a recombinant, nonglycosylated homolog of IL-1R that differs from native human IL-1R by the addition of a single methionine residue at its amino terminus. Anakinra blocks the activity of IL-1 by competitively inhibiting IL-1 binding to the IL-1RI receptor (Figure 63-2). Levels of the naturally occurring IL-1R, which are elevated in the synovium and synovial fluid from RA patients, are insufficient for the excess amount of locally produced IL-1.

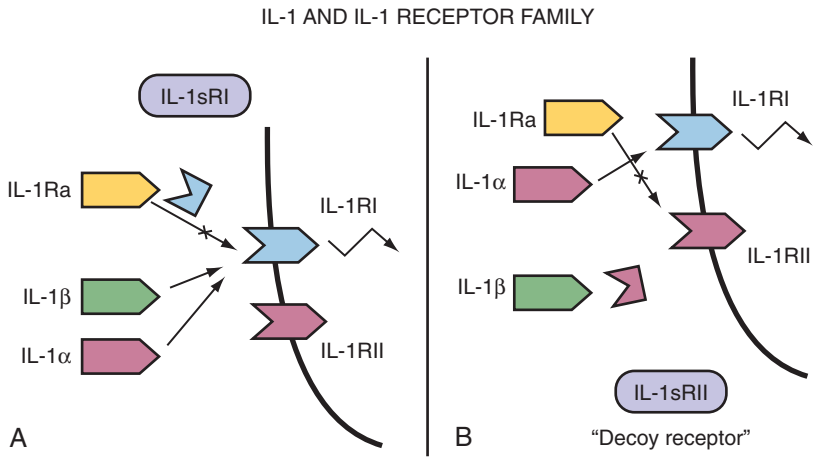

**Figure 63-2** **A** and **B,** Anakinra. Structure and mechanism of action: anakinra is a recombinant, nonglycosylated homologue of interleukin-1. It blocks the activity of IL-1 by competitively inhibiting IL-1 binding to the IL-1RI receptor (see Chapter 26). In addition, IL-1Ra can also bind to the soluble IL-1 receptors.

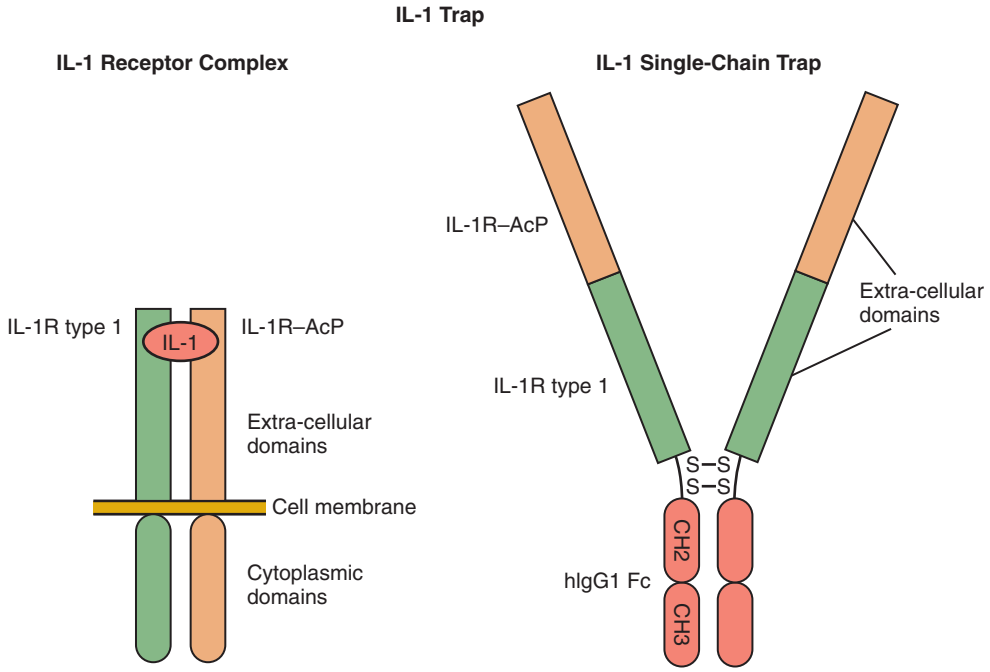

**Figure 63-3** Rilonacept. Structure: Rilonacept is a fusion protein consisting of the human interleukin (IL)-1 receptor extra-cellular domains and the Fc portion of human immunoglobulin G1. CH2, CH3, Constant domains of human immunoglobulin G1; hIgG, human immunoglobulin G; IL-1R–AcP, interleukin-1 receptor accessory protein.

## Pharmacokinetics

In patients with RA, maximum plasma concentrations of anakinra occur 3 to 7 hours after the subcutaneous administration of clinically relevant doses (1 to 2 mg/kg). The terminal half-life ranges from 4 to 6 hours. In RA patients, no unexpected accumulation of anakinra is observed after daily subcutaneous doses for as long as 24 weeks. Estimated anakinra clearance increases with increasing creatinine clearance and body weight.

## Drug Dose

The recommended dose of anakinra for the treatment of patients with moderately to severely active RA is 100 mg/day administered by subcutaneous injection. Anakinra can be used alone or in combination with MTX. Because of the potential for increased risk of infection, it is not recommended for use in conjunction with TNF inhibitors.

**Rilonacept.** Rilonacept, previously known as *IL-1 Trap*, is a fusion protein consisting of the human IL-1 receptor extra-cellular domains and the Fc portion of human IgG1. It incorporates in a single molecule the extra-cellular domains of both receptor components required for IL-1 signaling: IL-1RI and the IL-1R accessory protein (Figure 63-3). Rilonacept has a very high binding affinity for IL-1 (dissociation constant ~1 pM), and it is specific for IL-1β and IL-1α. It is administered subcutaneously with a loading dose of 320, followed by 160 mg once weekly.

Canakinumab. Canakinumab is a human monoclonal antibody that selectively targets IL-1β. It has no cross-reactivity with other members of the IL-1 family, including IL-1α. It is given subcutaneously 150 mg every 8 weeks to patients weighing greater than 40 kg. For patients whose body weight is between 15 and 40 kg, the recommended dose is 2 mg/kg.

### Efficacy

**Rheumatoid Arthritis.** Preliminary clinical studies indicated that anakinra could be safely administered by subcutaneous injection. The efficacy of anakinra in the treatment of active RA was confirmed in a 24-week, phase II, placebo-controlled study with three different doses of anakinra (30, 75, or 150 mg).[88] Improvements were observed in patients in all individual clinical parameters, including swollen and tender joint counts, pain score, duration of early morning stiffness, and patient and physician assessment of disease activity. More patients on the higher dose of anakinra achieved improvement in ACR20 criteria compared with the placebo group. However, the overall magnitude of the reduction in clinical symptoms and signs (20% to 30%) was relatively modest compared with that seen with TNF-blocking agents (60% to 70%). Patients were allowed to go on to a non–placebo-controlled extension study with three different doses of anakinra after completing the 24-week double-blind study. On completion of the extension study, 55% of patients who had previously received placebo achieved an ACR20 response. Of the patients who continued receiving the same dose of anakinra, 49% maintained an ACR20 response at 48 weeks. Analysis of hand radiographs by two different methods after 24 weeks of treatment showed a statistically significant decrease in the rate of progressive joint damage compared with placebo.[89] Improvements in functional status and quality of life were also observed.[90]

Anakinra is a competitive inhibitor of IL-1 that must be continuously present in great excess to be effective, and it must be administered daily. It was hypothesized that the relatively modest clinical results seen with anakinra in patients with RA (compared with those achieved by TNF inhibitors) might be related to the agent rather than to the target. Two lines of evidence appear to refute this hypothesis: the efficacy of anakinra in other inflammatory diseases, and the comparable clinical efficacy of other IL-1 inhibitors in RA.

Based on early studies, the subcutaneous administration of rilonacept in subjects with RA provided evidence of its clinical and biologic activity. However, a double-blind, placebo-controlled clinical trial in patients with moderate to severe RA who were randomly assigned to receive weekly injections of placebo or several doses of rilonacept for 12 weeks showed only modest efficacy.[91]

Canakinumab reduced disease activity in patients with new-onset RA, including patients who failed to benefit from TNF-blocking therapies. However, the long-term benefits and radiologic changes remain unstudied.

**Autoinflammatory Diseases.** Systemic autoinflammatory diseases are rare syndromes that have common systemic manifestations, such as fever, neutrophilia, arthralgias, myalgias, and severe fatigue, that are generally periodic rather than progressive. Familial Mediterranean fever is perhaps the most well-known autoinflammatory disease. Patients with familial cold autoinflammatory syndrome (FCAS) might be seen with a spectrum of disease activity: neonatal-onset multisystem inflammatory disease (NOMID; also known as *chronic infantile neurologic, cutaneous, articular syndrome* [CINCA]), Muckle-Wells syndrome (MWS), and familial cold urticaria. These conditions, share some clinical features, and are associated with various mutations in the *NALP3/CIAS1/PYPAF1* gene, which encodes the protein cryopyrin. Cryopyrin is a key component of the inflammasome; thus the autoinflammatory syndromes may be related to abnormalities in IL-1 regulation. This was proven by the remarkable responses to anakinra reported in these syndromes. In addition, significant and rapid responses have been achieved when anakinra was used to treat patients with adult-onset Still's disease. Improvement in various hematologic, biochemical, and other markers suggests that IL-1 plays a key role in this disease as well. Often, on blocking IL-1β, patients with cryoprin-associated periodic syndromes (CAPS) and other autoinflammatory diseases experience a rapid and sustained cessation of symptoms as well as reductions in biochemical, hematologic, and functional markers of their disease. Because treatment with rilonacept and cakinumab are equally effective in treating autoinflammatory diseases, the culprit in these disease is in IL-1β and not IL-1α.

Rilonacept and canakinununumab are approved for CAPS disorders: FCAS and MWS.[92,93] Canakinumab is also approved for systemic juvenile idiopathic arthritis. Anakinra is the first and only drug that is approved for the treatment of children and adults with NOMID, the most severe form of CAPS.

### Gout

Some patients with recurrent attacks of gouty arthritis who are resistant to colchicine and NSAIDs require steroids to control the disease flares. When treated with anakinra, rilonacept, and canakinumab, a rapid, sustained, and remarkable reduction in inflammation and pain has been observed, and in fact this effect seems to be superior to steroids.[94] IL-1 blockers' effect on controlling gout attacks is currently being investigated in clinical trials.

### Other Disorders

IL-1 blockers are under investigation in various disorders, including stroke, indolent myeloma, type 1 and 2 diabetes, osteoarthritis, and graft-versus-host disease (GVHD).

## Other Considerations

### Toxicity

Anakinra is generally well tolerated. Injection site reactions are the most frequently reported adverse event. In a randomized clinical trial, injection site reactions were reported in 25% of patients given placebo and in 50%, 73%, and 81% of patients given anakinra in doses of 30, 75, and 150 mg/day, respectively.[95] These reactions were generally mild and transient. Infections were uncommon and occurred

at a similar rate in the placebo and treatment groups. Infections that required antibiotic therapy occurred in 12% of the placebo-treated group and in 15% to 17% of the treatment group. These infections consisted primarily of bacterial events such as cellulitis and pneumonia. The incidence of pulmonary infection appeared to be higher among patients with underlying asthma. In placebo-controlled studies, as many as 8% of patients receiving anakinra showed a reduction in the neutrophil count, compared with 2% of patients in the placebo group. Other adverse events reported were headache, nausea, diarrhea, sinusitis, influenza-like syndrome, and abdominal pain. Malignancy rate and incidences were similar to those expected for the populations studied. Long-term follow-up of patients on anakinra has proved the overall tolerability of therapy during several years.

In animal studies, the combination of TNF inhibition and IL-1 inhibition achieved synergistic efficacy in arthritis models. However, when this approach was tested in RA patients, the combination did not achieve any additional clinical benefit but did result in greater toxicity—specifically, an increased incidence of infection and serious infection.[96] Therefore the combination of biologic therapies targeting TNF and IL-1 is currently not recommended.

### Monitoring

Patients should be closely monitored for signs and symptoms of infection. Administration of anakinra must be discontinued if serious infection develops in a patient. Neutrophil counts should be assessed before anakinra treatment is initiated, as well as monthly during anakinra therapy for 3 months, and then every 4 months for as long as 1 year.

### Pregnancy and Breastfeeding

Reproductive studies have been performed only on rats and rabbits, and they have not revealed any evidence of harm to the fetus. However, no well-controlled studies have been conducted in pregnant women. Therefore anakinra should be used during pregnancy only if it is clearly needed. It is not known whether anakinra is secreted in human milk, so it should be discontinued in nursing mothers.

## INTERLEUKIN-6

IL-6 and other members of the IL-6 cytokine family play a critical role in inflammatory and immune responses. IL-6 is a small polypeptide characterized by a four–α-helix bundle structure that is stabilized by intramolecular disulfide bridges. IL-6 is secreted by various cell types, including monocytes, T and B lymphocytes, and fibroblasts. It is detectable at elevated levels in the serum and synovial tissue in inflammatory arthritides, including RA and PsA. IL-6 exerts its activity by binding its receptor component, IL-6R, which exists in soluble and membrane-bound forms, and the accessory protein, glycoprotein 130 (gp130). The IL-6R is constitutively expressed on several cell types, including lymphocytes and hepatocytes. However, soluble forms of IL-6R can productively interact with the 130 kDa signal transducing component gp130, which is expressed on a wide range of cell types (Figure 63-4). IL-6 has multiple effects on various aspects of the immune system to initiate inflammation. IL-6 stimulates the production of T helper (Th)17 cells. These pathogenic cells secrete IL-17 and are involved in the induction of autoimmune injury. IL-6 also plays a role in B cell activation and differentiation. Effects of IL-6 on osteoclast differentiation and activation, including receptor activator of NF-κB (RANK) ligand–dependent mechanisms, have been clearly demonstrated.[97] Recruitment of neutrophils to the inflammatory sites and stimulation of VEGF synergistically with TNF and IL-1β contribute to pannus formation.[98] Levels of IL-6 are directly proportionate with levels of CRP and disease severity. IL-6 knockout mice are resistant to CIA and show reduced levels of serum TNF. All these functions make IL-6 blockade an

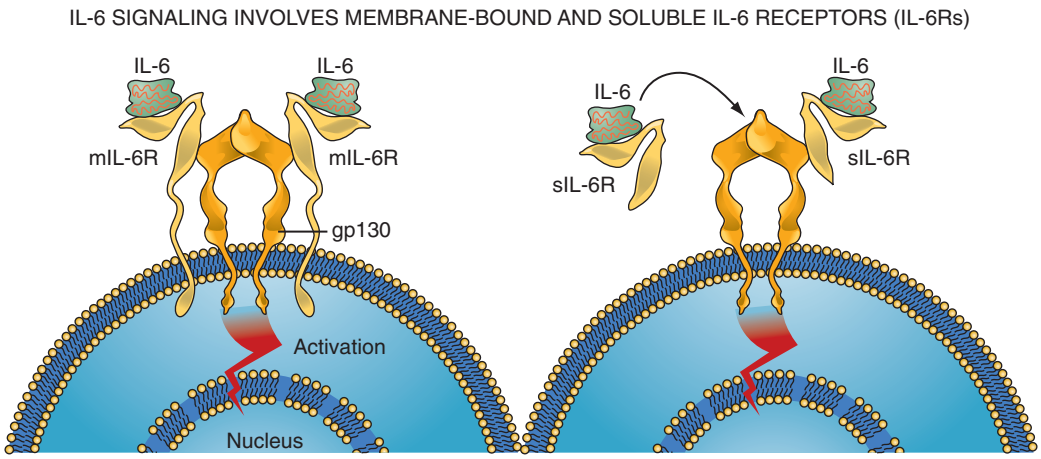

**Figure 63-4** Interleukin (IL)-6. Mechanism of action: IL-6 binds first to the membrane-bound IL-6 receptor (mIL-6R). The IL-6/mIL-6R complex then associates with the signal-transducing membrane protein, glycoprotein 130. IL-6 can also bind to sIL-6Rs which, in turn, can interact with gp130 and activate signaling *(right)*.

attractive biologic target therapy for the treatment of RA and other autoimmune diseases.

## Tocilizumab

### Structure and Mechanism of Action

Previously referred to as *myeloma receptor antibody* (MRA), tocilizumab is a humanized IgG1 monoclonal antibody that binds with high affinity to soluble and membrane-bound forms of the 80 kDa component of the IL-6R. Tocilizumab is a recombinant humanized anti–human IL-6 receptor monoclonal antibody of the immunoglobulin IgG1κ (gamma 1, kappa) subclass with a typical $H_2L_2$ polypeptide structure. Each light chain and heavy chain consists of 214 and 448 amino acids, respectively. The four polypeptide chains are linked intramolecularly and intermolecularly by disulfide bonds. Tocilizumab has a molecular weight of approximately 148 kDa. Treatment with this monoclonal antibody effectively inhibits IL-6–mediated interactions on cells constitutively expressing the IL-6R. In addition, as noted, soluble forms of the IL-6R can productively interact with the 130 kDa signal-transducing component gp130, which is expressed on a wide range of cell types; thus treatment with tocilizumab effectively inhibits a broad array of IL-6–driven processes.

### Pharmacokinetics

Tocilizumab has a nonlinear pharmacokinetic profile.[99] The maximum concentration increases in approximate proportion to increases in dosage, whereas the area under the concentration-time curve increases disproportionately. As the dosage increases, clearance and the apparent elimination rate constant decrease, and terminal half-life and mean residence times are prolonged. MTX therapy, alcohol consumption, age, and race do not affect the pharmacokinetics of tocilizumab. Tocilizumab binds to soluble IL-6R in a dose-dependent manner and saturates the receptor at approximately 0.1 μg/mL. Tocilizumab also competitively inhibits IL-6 binding to soluble IL-6R; complete inhibition is seen at approximately 4 μg/mL.

After IV dosing, tocilizumab undergoes biphasic elimination from the circulation. In patients with RA, the central volume of distribution was 3.5 L, and the peripheral volume of distribution was 2.9 L, resulting in a volume distribution at steady state of 6.4 L.

### Drug Dose

Indications for the use of tocilizumab vary across the globe. In the United States, initial approval for tocilizumab in late 2009 was for use as a single agent or with MTX or other DMARDs to treat adult patients with rheumatoid arthritis in whom one or more anti-TNF agents had failed. The recommended starting dose is 4 mg/kg, followed by an increase to 8 mg/kg based on clinical response. In other countries, it is recommended to start therapy at 8 mg/kg, with the possibility of reducing to 4 mg/kg, for example, in the case of tolerability concerns. It is administered once every 4 weeks as a 60-minute single intravenous infusion. Doses exceeding 800 mg per infusion are not recommended. Development of a preparation of tocilizumab for subcutaneous administration is under way.

### Efficacy

An early double-blind, placebo-controlled, randomized clinical trial revealed statistically significant ACR20 responses with 10 mg/kg and 5 mg/kg single infusions of tocilizumab when given to patients with active RA with no concomitant DMARDs.[99,100] Substantial decreases in measures of the acute phase response, including the erythrocyte sedimentation rate (ESR) and CRP concentration, were seen with 5 and 10 mg/kg as early as 1 week and were largely sustained through week 4. Larger phase II studies tested tocilizumab monotherapy, given at a dose of 4 mg/kg or 8 mg/kg intravenously every 4 weeks during 3 months, to patients with relatively refractory and active RA. Most individual measures of arthritis activity improved to a statistically significant level by week 4, and the extent of response continued to improve through 12 weeks. Sustained clinical responses were maintained for a considerable number of patients during 5 years of an open-label follow-up period.[101] In a large European study known as Chugai Humanized Anti–Human Recombinant IL-6 Monoclonal Antibody (CHARISMA) study, patients with active RA despite receiving MTX treatment for at least 6 months were randomly assigned to receive tocilizumab 2, 4, or 8 mg/kg every 4 weeks alone or in combination with their existing MTX. Another group received MTX alone. Patients on tocilizumab alone at doses of 4 and 8 mg/kg had improvement in ACR20; however, patients remaining on concomitant MTX with tocilizumab achieved statistically significant improvement at 16 weeks compared with those given MTX alone.[102] The ability of treatment with tocilizumab to alter the progression of joint damage was first assessed in patients with relatively early-stage RA in the Study of Active Controlled Monotherapy Used for Rheumatoid Arthritis, an IL-6 Inhibitor (SAMURAI).[103] Therapy with tocilizumab was shown to have a beneficial effect on the progression of radiographic joint damage defined by the total Sharp score, in addition to improvements in clinical and functional status.

Tocilizumab has been studied in series of multinational phase III clinical trials involving more than 4000 patients. In the OPTION trial, patients with moderate to severe RA who were MTX-inadequate responders received 4 mg/kg or 8 mg/kg tocilizumab or placebo every 4 weeks. Fifty-nine percent and 48% of patients who received tocilizumab 8 mg/kg and 4 mg/kg plus MTX, respectively, achieved ACR20 at week 24, compared with 27% of patients who received placebo plus MTX. Patients in the placebo and 4 mg/kg groups switched to the 8 mg/kg group (rescue therapy), and by week 24, all patients receiving tocilizumab had significantly better responses in all core set values, including DAS28, HAQ, pain visual analogue scale (VAS), and global VAS.[104] In the TOWARD trial, patients with active disease, despite being on stable doses of DMARDs (the most common being MTX) were randomized to receive monthly 8 mg/kg tocilizumab or placebo infusions. At 24 weeks, the tocilizumab group showed significantly improved ACR20 response rates and DAS28 scores, as well as HAQ and fatigue scores.[105] The AMBITION trial included

patients who were methotrexate naïve or who had discontinued MTX for reasons other than lack of efficacy or toxicity. Seventy percent of patients who received tocilizumab 8 mg/kg achieved ACR20 at week 24, compared with 53% of patients receiving MTX alone. ACR50 and -70 response rates, HAQ scores, and DAS28 remission were also superior in comparison with the MTX group.[106]

The efficacy of tocilizumab for the treatment of patients who had an inadequate clinical response or were intolerant to one or more anti-TNF agents was evaluated in a rheumatoid arthritis study in anti-TNF failures (RADIATE). Fifty percent and 30% of patients who received tocilizumab 8 mg/kg or 4 mg/kg plus MTX, respectively, achieved ACR20 at week 24, compared with 10% of patients who received placebo plus MTX. Of note, the number and type of TNF antagonists previously failed did not appear to affect the ACR20 response rate.[107] The Tocilizumab Safety and the Prevention of Structural Joint Damage (LITHE) trial is a long-term trial designed to evaluate the efficacy of tocilizumab for preventing structural damage in patients who had an inadequate response to prior MTX therapy. At week 24, 56% and 51% of patients who received tocilizumab 8 mg/kg or 4 mg/kg plus MTX, respectively, achieved ACR20 compared with 27% of patients who received placebo plus MTX. Mean joint erosion, joint space narrowing, and total Genant-modified Sharp scores indicated that both tocilizumab doses were associated with significant inhibition of radiographic progression from baseline compared with that of placebo.[108] Clinical, functional, and structural remission in patients with advanced RA was demonstrated in a 52-week trial. Forty-two percent of patients with remarkably severe RA with long disease duration and progressive joint damage achieved clinical remission.[109] Long-term treatment with tocilizumab as long as 4.2 years revealed increasing numbers of patients achieving ACR50 and -70 scores, DAS28 remission, and high retention rates.[79]

## Safety

A number of safety concerns are associated with blocking a major regulatory cytokine such as IL-6. These can be grouped as general immunomodulatory effects (e.g., infection), IL-6–related effects (e.g., abnormalities in liver enzymes, lipid profiles), and finally agent-specific effects (e.g., infusion reactions) (Table 63-3).

Infections are a concern, as they are with all immunomodulatory therapies for RA. In clinical trials of tocilizumab, the occurrence of infection appears compatible with that of other approved biologic agents. Although the overall infection rate with tocilizumab monotherapy was comparable with rates in MTX monotherapy groups, the incidence of overall infection was slightly higher with concomitant DMARD therapy. The most commonly reported infections (5% to 8%) were upper respiratory infections and nasopharyngitis. A similar incidence of serious adverse events (5%) was generally observed across study groups. Serious infections occurred more often in higher-dose groups as compared with the placebo group. Cellulitis, pneumonia, diverticulitis, gastroenteritis, and herpes zoster were the most common infections noted. Only rare cases of opportunistic infection have been reported.[102-104]

**TABLE 63-3** Adverse Effects Potentially Associated with Tocilizumab

| |
|---|
| **Immunomodulatory Effects** |
| Infections/serious infections |
| **Mechanism-based Effects** |
| Increased liver enzymes |
| Abnormalities in lipid profiles |
| Neutropenia |
| Low platelet count |
| Malignancies |
| Demyelinating conditions |
| Gastrointestinal perforations |
| **Agent-Related Effects** |
| Administration reactions |
| Hypersensitivity reactions |

Transient elevations of ALT and aspartate aminotransferase (AST) levels were commonly observed in tocilizumab-treated patients. Elevations were more apparent immediately following infusions, potentially reflecting blockade of the anti-apoptotic properties of IL-6 in hepatocytes. An increase in ALT levels to three or more times the upper limit of normal was noted in 5% to 6.5% of patients who received tocilizumab and concomitant DMARD therapy. These rates were 1.5% and 2.1% in patients who received only DMARD or only tocilizumab, respectively.[102,104-106] To date, elevated transaminases have not been associated with reduced liver function or serious adverse events.[98,102,105]

Lipid profiles were altered in the tocilizumab group compared with placebo. Tocilizumab was associated with increases in all lipid levels, including total cholesterol and its fractions, low-density lipoprotein (LDL) cholesterol, and high-density lipoprotein (HDL) cholesterol. Increases in these parameters were noted by the first assessment at 6 weeks and remained elevated through the clinical trials. Despite elevations in these parameters, clinical cardiovascular events have not increased in clinical trials. Mean increases in the 8 mg/kg tocilizumab plus DMARD group were 30.9 mg/dL (total cholesterol), 21.7 mg/dL (LDL cholesterol), 4.3 mg/dL (HDL cholesterol), and 30.1 mg/dL (triglycerides).[104,105]

A higher proportion of patients receiving tocilizumab had a decrease in neutrophil counts (29%) in comparison with patients who were not receiving this drug (4%). The drop in neutrophil counts was generally mild (grade 1, according to the common toxicity criteria, i.e., 1500 to 2000 cells/$mm^3$ or more) to moderate (grade 2, 1000 to 1500 cells/$mm^3$) in severity and reversed with discontinuation of treatment. To date, no clear association between low neutrophil counts and infection-related adverse events has been noted.[99,104,105]

Treatment with tocilizumab was associated with a reduction in platelet counts. The decrease in platelet counts was below the lower limit of normal and was reported in 8% to 9% of patients receiving tocilizumab with or without MTX. However, no serious bleeding incidents occurred. Only

isolated cases of epistaxis and hemoptysis were reported in patients with moderate to severe thrombocytopenia.

Rare events of gastrointestinal perforation have been reported in clinical trials, primarily as complications of diverticulitis. The overall rate of gastrointestinal perforation was 0.26 event per 100 patient-years. Most patients in whom gastrointestinal perforations developed were taking concomitant NSAIDs, corticosteroids, or MTX. Patients presenting with new-onset abdominal symptoms therefore should be evaluated promptly for early identification of gastrointestinal perforation.

Because tocilizumab is a humanized antibody, infusion-related adverse events might be expected. Adverse reactions associated with the infusion were reported to be 8% and 7% in patients receiving 4 mg/kg and 8 mg/kg tocilizumab together with MTX. The most commonly reported adverse events were hypertension during the infusion and headache and skin reactions within 24 hours after the infusion. These reactions did not result in termination of treatment. Antibodies to tocilizumab were detected in a small group of patients, and very few were associated with medically significant hypersensitivity reactions that led to withdrawal. The development of antibodies and of infusion reactions may be greater among patients receiving the lower dose of tocilizumab.

Rates of malignancy were similar in the tocilizumab- and DMARD-treated groups. Rare cases of demyelinating disorders were reported in clinical trials. Long-term experience with tocilizumab will determine the actual risk for these entities; however, caution needs to be exercised in patients with any risk factors for malignancy or demyelinating disorders.

A systematic literature search on six published randomized controlled trials that assessed the risk of adverse events with tocilizumab revealed that tocilizumab in combination with MTX as a treatment for RA is associated with a small but significantly increased risk of adverse events, which is comparable with that of other biologics. The risk of infection was significantly higher in the 8 mg/kg combination group compared with controls (odds ratio, 1.30; 95% CI, 1.07 to 1.58). No increased incidence of malignancy, tuberculosis reactivation, or hepatitis was seen.[110]

### Drug Interactions

IL-6 inhibition might affect cytochrome P450 substrates. In vivo studies showed that omeprazole and simvastation levels decreased by 28% and 57%, respectively, 1 week after tocilizumab infusion. Upon initiation or discontinuation of tocilizumab, drugs with a narrow therapeutic margin, such as warfarin or drug concentrations of certain drugs such as cyclosporine, should be closely monitored.

Tocilizumab has not been studied, and its use should be avoided in combination with biologic DMARDs, such as TNF blockers, IL-1 blockers, anti-CD20 monoclonal antibodies, and co-stimulation blockers.

It is recommended that live vaccines should not be given concurrently with tocilizumab because clinical safety has not been established. It would be desirable for patients to be brought up to date on all recommended vaccinations before treatment with tocilizumab is initiated.

### Monitoring

Patients should be evaluated for tuberculosis and other infections before treatment with tocilizumab is begun. Antituberculosis therapy should be initiated before tocilizumab is started in patients with active tuberculosis.

It is not recommended to initiate tocilizumab treatment in patients who have ALT and AST levels greater than 1.5 times the upper level of normal or any evidence of liver disease. For all patients, liver function tests should be repeated initially every 4 to 8 weeks during tocilizumab treatment. When the ALT or AST level is between one and three times the upper level of normal, the dose of tocilizumab or concomitant DMARD should be adjusted. For persistent increases in this range, the tocilizumab dose should be modified. If the ALT or AST level is greater than three to five times the upper level of normal, tocilizumab should be interrupted until the level falls below three times the upper level of normal. For ALT or AST elevations greater than five times the upper level of normal, the drug should be discontinued.

Patients receiving tocilizumab should have lipid levels monitored with a goal toward maintaining levels within the target ranges of National Cholesterol Education Program Adult Treatment Panel III or local guidelines. Patients should be managed with lipid-lowering agents if appropriate.

Caution should be exercised when tocilizumab is initiated in patients with a very low neutrophil count at baseline, and all patients should have their absolute neutrophil count (ANC) monitored 4 to 8 weeks after the first infusion. It has been recommended that tocilizumab should not be administered to patients with ANC values less than 2000 cells/mm$^3$. If the ANC falls to between 500 cells/mm$^3$ and 1000 cells/mm$^3$, drug therapy should be discontinued until the ANC reaches above 1000 cells/mm$^3$.

It is not recommended to initiate tocilizumab treatment in patients with a platelet count below 100,000/mm$^3$. Treatment with tocilizumab should be interrupted if the platelet count falls to below 50,000/mm$^3$. Platelets should be monitored every 3 to 8 weeks.

### Pregnancy and Breastfeeding

No adequate and well-controlled studies have been conducted in pregnant women. Therefore tocilizumab is a Pregnancy Category C drug and should be used only if potential benefits justify potential risk to the fetus. It is not known whether tocilizumab is excreted in human milk or is absorbed after oral ingestion.

### Other IL-6 Blockers

**Sarilumab.** Sarilumab is human monoclonal antibody directed against the IL-6 receptor. It showed efficacy in two different doses (150 mg and 200 mg) given subcutaneously every 2 weeks in the MOBILITY studies.[111]

**Sirukumab.** A human monoclonal anti–IL-6 monoclonal antibody, sirukumab has also shown improvements in signs/symptoms of RA when given 100 mg subcutaneously every 2 weeks.[112]

### Emerging Therapies

**IL-17 Blockers.** Rheumatoid synovial tissue produces 1L-17A, which causes cartilage and bone degradation in synovial and bone explants. Serum IL-17 levels and synovial fluid levels are elevated in many patients with RA. Several IL-17A blockers, including the anti–IL-17 monoclonal antibodies secukinumab and ixekizumab, and the IL-17 receptor subunit A monoclonal antibody brodalimumab have been evaluated in RA.[113] Despite the sound immunopathologic rationale in RA, clinical efficacy with IL-17 inhibitors has been modest at best. This result stands in distinction to the dramatic efficacy of IL-17 inhibition in psoriasis. By 2016, secukinumab was approved for psoriatic arthritis and anklyosing spondylitis. The relative position of this and other IL-17 blocking strategies in the therapeutic armamentarium will require additional study.

**B cell—Targeted Therapies.** Following the success with B cell depletion with rituximab, alternative targets are being studied. B lymphocyte stimulator (BLyS) and proliferation-inducing ligand (APRIL) are two TNF family cytokines which play an important role in regulation of B cell maturation, proliferation, function, and survival. TACI, BCMA, and BAFF are the receptors that have unique binding properties for BLyS and APRIL. Belimumab, atacicept and tabalumab are BAFF/BLyS inhibitors (and APRIL, in the case of atacicept) that had been investigated in RA. However, due to low efficacy and potential toxicity, the development plans for these agents in RA were suspended. Belimumab has demonstrated modest efficacy in SLE and has been approved for use in the United States (see Chapter 81).[114]

## CONCLUSION

Treatment of patients with RA with inhibitors of key proinflammatory cytokines TNF, IL-1, and IL-6 is a compelling example of effective targeted biologic therapy. Treatment with these agents, particularly TNF inhibitors, has substantially improved the signs and symptoms of disease. For many patients, quality of life has been improved, the progression of joint damage has been inhibited, and disability has been averted. The success of this approach has "raised the bar" for the goals of treating this pernicious disease and has reinvigorated research aimed at further refinements of therapy. It has also stimulated research into the potential utility of inhibitors of additional cytokines, such as IL-6, IL-15, and IL-18, and other components of the immune system relevant to autoimmune disease.

A number of questions remain regarding the optimal use of these drugs. Longer-term safety data will allow clinicians to more fully assess the risk-benefit ratio for individual patients. Given uncertainties regarding the long-term safety of these drugs and the heterogeneity of clinical responses, research defining the populations of patients expected to derive the greatest benefit with the least toxicity is critical. For example, ongoing research assessing genetic polymorphisms or proteomic differences among treated patients could optimize efficacy while minimizing toxicity. This is also relevant from a cost standpoint. Although the acquisition costs of these agents are relatively high, data supporting their cost-effectiveness, including gains in employment and reduced hospitalizations, are emerging.[115]

The success observed with these biologic therapies has raised additional clinical questions. For example, can very early treatment with highly effective therapy, such as the combination of TNF inhibitor and MTX, truly alter the disease course? What might the optimal treatment paradigms be for various rheumatic diseases? The success of the TNF inhibitors has also generated substantial interest in targeting this cytokine by alternative approaches, including inhibition of key regulatory factors, such as p38 mitogen-activated protein kinase and NF-κB. Advances in biopharmaceuticals could generate agents that possess desirable characteristics in terms of pharmacokinetics, immunogenicity, adverse effects, ease of administration, and cost. These developments should eventually allow clinicians to maximize the use of these novel therapies and achieve clinical benefits that previously were considered unattainable.

CHAPTER 64

# Cell-Targeted Biologics and Emerging Targets: Rituximab, Abatacept, and Other Biologics

Peter C. Taylor

**KEY POINTS**

- Rituximab is an effective biologic therapy across the spectrum of rheumatoid arthritis (RA) patient populations but with greatest benefit in seropositive patients. Clinical trials in persons with active, established RA confirm that a single cycle of rituximab given as two infusions of 1 g each, together with once-weekly oral methotrexate, produces an enduring clinical response comparable to that observed with tumor necrosis factor (TNF) blockade. A treatment cycle of two infusions of 500 mg is also efficacious but may result in a lower proportion of patients demonstrating more robust clinical responses and is less likely to inhibit radiographic progression.
- Current data suggest that the most appropriate interval between rituximab courses is 6 to 12 months. Repeat treatment produces American College of Rheumatology (ACR) responses that equal or exceed those from the first course of treatment, with a comparable duration of effect.
- Rituximab has an acceptable safety record in RA trials, but infusion reactions of variable severity can occur; most are mild to moderate. Frequency and severity are reduced by the administration of intravenous methylprednisolone before rituximab infusions.
- Clinical trials in patients with active, established RA confirm that abatacept can result in a meaningful clinical response within 16 weeks.
- Abatacept represents an effective biologic therapy with acceptable safety across the spectrum of RA patient populations. Sustained clinical responses may be incremental for up to 2 years of treatment.
- The benefit-risk profile of abatacept may be most optimal when it is introduced earlier in the RA treatment paradigm. Both rituximab and abatacept slow radiographic progression in patients with RA.
- Current uncertainties include the lack of reliable biomarkers to inform the rational choice of a biologic agent.

As appreciation of the gravity of the social and economic burden imposed by rheumatoid arthritis (RA) has grown, so has the recognition that more favorable clinical outcomes are achieved when synovitis is optimally suppressed. The evidence is particularly compelling early in the course of RA, when intervention with disease-modifying combination therapy results in improved remission rates and increased clinical and radiographic benefits.[1-3] The armamentarium of potential therapeutics has also grown with the identification of relevant disease molecules. Of these, biologic therapeutics targeting tumor necrosis factor (TNF), particularly when used in combination with oral methotrexate, have had notable success in suppressing inflammation and markedly inhibiting the progression of structural damage previously thought to be an unavoidable characteristic of RA.[4,5] However, despite the unprecedented clinical and commercial successes of TNF inhibitors, their availability is restricted by high costs. In addition, a substantial proportion of patients with RA do not demonstrate significant clinical responses.

An entirely different treatment approach to the blockade of pro-inflammatory cytokines is the targeting of cells implicated in the persistence of RA. It is believed that immune responses drive the disease process in RA, and because chronicity is a hallmark of the RA phenotype, it presumably reflects the persistence of immunologic memory, which is induced and maintained by the adaptive immune system. In particular, T and B cells develop highly specific receptors and, after stimulation, expand enormously in number and then persist for long periods. If this is true of aberrant immune responses that lead to disease, then T and B cells represent rational targets for immune intervention. The focus of this chapter is on biologic agents with specificity for cellular targets, namely cell surface molecules associated with B cell subsets, most notably CD20, and co-stimulation molecules expressed on antigen-presenting cells that recognize cognate ligands on T cells. Two drugs that have become an accepted part of the pharmacologic armamentarium for RA treatment will be emphasized: rituximab and abatacept. Rituximab (Rituxan, Genentech, South San Francisco, Calif., and Biogen Idec, Cambridge, Mass.; MabThera, F. Hoffman-LaRoche AG, Basel, Switzerland) is an antibody that selectively depletes a B cell subset that expresses the CD20 antigen. Other biologic agents targeting this antigen that have been in clinical trials are the humanized monoclonal antibody ocrelizumab and fully human monoclonal antibody ofatumumab. Abatacept (Orencia, Bristol-Myers Squibb, New York, N.Y.) is a fusion protein that selectively modulates a co-stimulatory signal necessary for T cell activation. Rituximab is approved in the United States and Europe for use in combination with methotrexate to reduce the signs and symptoms of RA in adult patients who have moderately to severely active disease and have not responded to one or more anti-TNF drugs. Abatacept is the first selective co-stimulation modulator to be approved in the United States and Europe for the treatment of patients with RA

who have an inadequate response to other nonbiologic or biologic disease-modifying anti-rheumatic drugs.

## TARGETING B CELLS

**KEY POINT**

**B cells are major contributors to RA pathogenesis, but their precise roles in the induction and maintenance of abnormal immune activation remain poorly understood.**

The role of B cells in the pathogenesis of RA is not fully understood. Nonetheless, there are a number of known B cell functions of likely relevance, including their role in antigen presentation, secretion of pro-inflammatory cytokines, production of rheumatoid factor and thus immune complex formation, and co-stimulation of T cells. Of note, immune complexes are an important trigger to the production of TNF and other pro-inflammatory cytokines. B cells are also implicated in the process of ectopic lymphoid organogenesis in the rheumatoid synovium.

B cells arise from stem cells in the bone marrow, where they acquire an antibody receptor bearing a unique variable region. A number of maturation and activation steps take place as the B cells migrate from the marrow compartment, through blood, and to perifollicular germinal centers and memory compartments in lymphoid tissue before returning to the marrow as mature plasma cells.[6] Successful maturation and survival of cells are tightly regulated and dependent on a number of trophic signals delivered via cell surface ligands, such as vascular cell adhesion molecule-1 (VCAM-1), and soluble factors, such as B lymphocyte stimulator (BLyS).[7,8]

In the late 1990s, Edwards and colleagues[9,10] suggested that the (assumed) underlying autoreactive response in RA might be driven by self-perpetuating B cells and that the initiation of inflammation results from ligation of the low-affinity immunoglobulin G (IgG) receptor FcRγIIIa by immune complexes. An attractive feature of this hypothesis, particularly in seropositive patients, is that it might account for the tissue tropisms of disease expression in the RA syndrome complex, because FcRγIIIa is expressed in high levels in synovium and other extra-articular tissues that may be involved in RA. Rheumatoid factor–producing cells can capture antibodies bound to antigen before antigen internalization by endocytosis and subsequent presentation of peptide fragments to a T cell, with provision of T cell help to the B cell. Edwards and Cambridge[11] also proposed that such rheumatoid factor–producing B cells might become self-perpetuating by an amplification signal arising from co-ligation of the B cell receptor and small immune complexes formed by IgG rheumatoid factor bound to the complement component C3d, providing a survival signal. In contrast, co-ligation of certain other B cell surface receptors with the B cell receptor may provide a negative survival signal. In the rare event that self-perpetuating, autoreactive B cells arise, having escaped normal regulatory mechanisms, this theory predicts that a B cell depletion strategy would remove the autoreactive B cell clones and their antibody products. Because CD20 is not internalized and is highly expressed on a range of B lineage cells, including pre–B cells, immature B cells, activated cells, and memory cells, but is not found on stem, dendritic, or plasma cells (Figure 64-1), it is an ideal target for B cell depletion by monoclonal antibodies. The hypothesis that B cells represent a therapeutic target in RA is also being tested in the clinic using other strategies for B cell inhibition, as discussed later.

The CD20 antigen is located in the B cell membrane, with 44 amino acids exposed to the extra-cellular space. Its function is unknown, although it may have a role in cell signaling or in calcium mobilization.[12] Interestingly, CD20 knockout mice do not have a clear-cut phenotype or obvious B cell defect.[13] $CD20^+$ B cells represent a prominent population in the rheumatoid synovial tissue in most patients.

## RITUXIMAB AND RHEUMATOID ARTHRITIS

**KEY POINT**

**Rituximab is a depleting chimeric monoclonal antibody lytic for a population of B cells expressing CD20.**

Rituximab is a chimeric mouse-human monoclonal antibody directed against the extra-cellular domain of the CD20 antigen. It initiates complement-mediated B cell lysis and may permit antibody-dependent, cell-mediated cytotoxicity when the Fc portion of the antibody is recognized by corresponding receptors on cytotoxic cells. Rituximab may also initiate apoptosis[14] and influence the ability of B cells to respond to antigen or other stimuli.[15] Rituximab initially

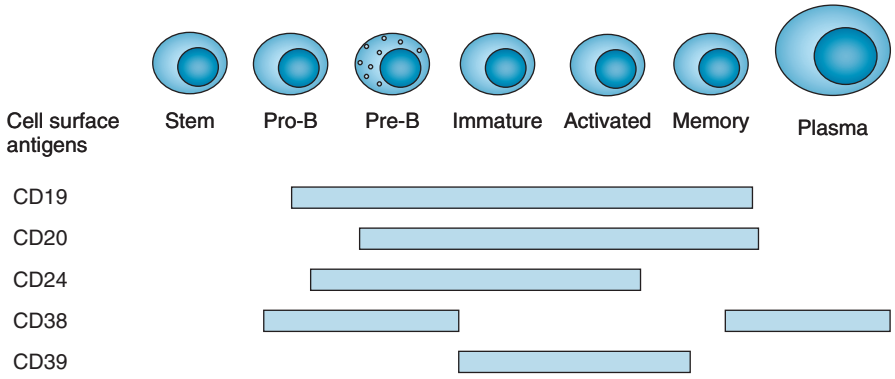

**Figure 64-1** Expression of the CD20 antigen on B lineage cells.

found a role in the clinic as a single-agent treatment for relapsed or refractory low-grade or follicular CD20+ B cell non-Hodgkin's lymphoma, for which it was approved. For this reason, there was wide experience with rituximab in hematologic oncology before initiation of clinical trials in RA and the approval of rituximab in the United States and Europe for the treatment of TNF inhibitor–refractory patients with RA who have active disease.

After rituximab administration, rapid B cell depletion takes place in peripheral blood, and conventional methods for measurement of peripheral blood B cells by means of CD19 expression detect no cells at all in most cases. Investigation of synovial tissue from patients with RA who are treated with rituximab reveal a decrease in synovial B cells and plasma cells in most though not all patients.[16,17] These findings raise the possibility that the inflamed synovium might contain as yet poorly understood rescue mechanisms that provide survival niches or, alternatively, that some B cells may have an inherent resistance against depletion.

Analysis of peripheral blood memory B cells before depletion, during depletion, and after reconstitution seems to be predictive of clinical outcome, with patients who show early relapses having substantially higher IgD+ and IgD-CD27+ memory B cell numbers and proportion during B cell recovery.[18] In addition to these cellular biomarkers, serologic parameters have been analyzed.

Decreases in rheumatoid factor (RF) or anti-citrullinated protein antibody (ACPA) serum levels are reported to be associated with B cell depletion,[19] but further studies are needed to determine the relationships between these serologic changes and clinical response.

## Clinical Studies

**KEY POINTS**

**Rituximab is an effective biologic therapy across the spectrum of RA patient populations.**

**Rituximab appears to have greatest benefit in seropositive patients.**

**Clinical trials in patients with active, established RA confirm that a single cycle of rituximab given as two infusions of 1 g each, together with once-weekly oral methotrexate, produces an enduring clinical response. A treatment cycle of two infusions of 500 mg is also efficacious but may result in a lower proportion of patients demonstrating more robust clinical responses.**

The findings of early clinical studies of B cell depletion therapy in patients with active RA using rituximab in a number of different treatment regimens suggested an encouraging benefit with an acceptable safety profile and pointed to a possible therapeutic role for rituximab in persons with RA.[20-22] However, confirmation of benefit required a randomized, double-blind, controlled study. In a phase IIa study, the efficacy of rituximab in persons with active RA was tested in 161 patients who had failed to respond adequately to methotrexate at a dose of at least 10 mg a week for a minimum of 16 weeks.[23] Patients were assigned to one of four treatment regimens: a 1-g infusion of intravenous rituximab alone on days 1 and 15, methotrexate alone as a comparison arm, intravenous rituximab with cyclophosphamide infusions at a dose of 750 mg on days 3 and 17, or rituximab and methotrexate. All patients received 100 mg of methylprednisolone just before each treatment, in addition to prednisolone, 60 mg daily, on days 2, 4, 5, 6, and 7, and 30 mg daily on days 8 to 14. The primary endpoint was the proportion of patients achieving an American College of Rheumatology (ACR)50 response at week 24, and exploratory analyses were undertaken at week 48. At week 24, a significantly greater proportion of patients achieved an ACR50 in the rituximab and methotrexate combination group (43%; $P = 0.005$) and in the rituximab and cyclophosphamide combination group (41%; $P = 0.005$) than in the group receiving methotrexate as monotherapy (13%) (Table 64-1). Thirty-three percent of the patients receiving rituximab alone achieved an ACR50 response, but this outcome failed to reach statistical significance compared with methotrexate alone ($P = 0.059$). In all the rituximab groups, the mean change from baseline in disease activity score was significant compared with methotrexate alone.

At 48 weeks, exploratory analyses indicated ACR50 and ACR70 responses in 35% and 15%, respectively, of patients in the rituximab and methotrexate group, which was significantly greater than the 5% and 0% responding at the corresponding levels in the methotrexate group. In the rituximab and cyclophosphamide treatment arm, 27% of patients achieved an ACR50 response.

Rituximab treatment was associated with near-complete peripheral blood B cell depletion that persisted throughout the 24-week period of the primary analysis. Patients in the rituximab groups had a substantial and rapid reduction in the concentration of rheumatoid factor in serum, but despite peripheral B cell depletion, immunoglobulin levels did not change substantially.[23] The overall incidence of infection was similar in the control and rituximab groups at 24 and 48 weeks. By week 24, four patients in the rituximab groups and one patient in the control group had acquired a serious infection. Two additional serious infections were reported during the extended 48-week period in the rituximab groups, one of which was fatal. Infusion reactions of any type were reported in 36% of patients receiving rituximab and 30% of patients receiving placebo, although most were

**TABLE 64-1** Percentage of Patients Achieving Responses at 24 Weeks in the DANCER and REFLEX Studies

| Study | Drug Regimen | ACR20 | ACR50 | ACR70 |
|---|---|---|---|---|
| Phase IIa Thurlings et al[19] | 1 g rituximab × 2 + methotrexate | 73 | 43 | 23 |
| | Methotrexate | 38 | 13 | 5 |
| Phase IIb DANCER[20] | 1 g rituximab × 2 + methotrexate | 54 | 34 | 20 |
| | Methotrexate | 28 | 13 | 5 |

| | Methotrexate | 18 | 5 | 1 |

ACR, American College of Rheumatology; DANCER, Dose-ranging Assessment: International Clinical Evaluation of Rituximab in Rheumatoid Arthritis; REFLEX, Randomized Evaluation of Long-term Efficacy of Rituximab in Rheumatoid Arthritis.

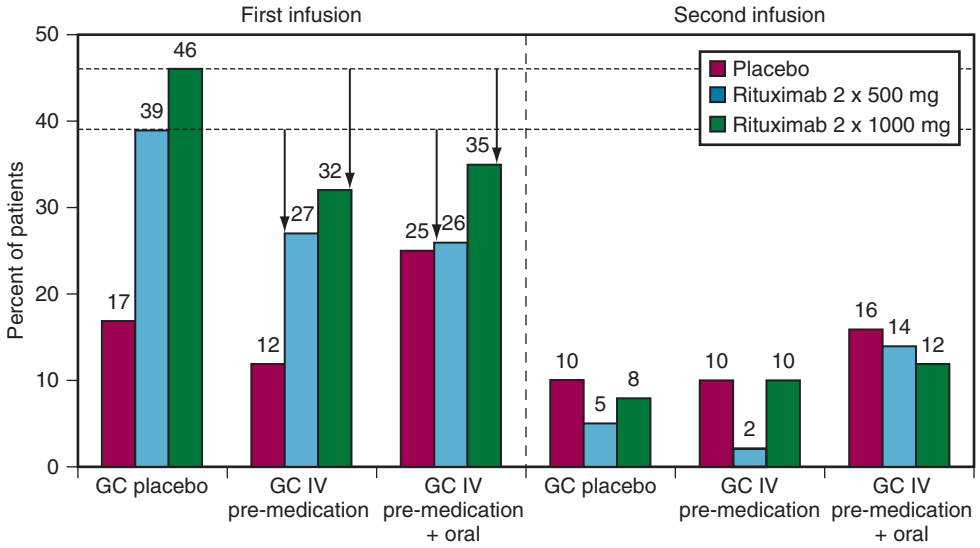

**Figure 64-2** The occurrence of infusion reactions in the DANCER (Dose-ranging Assessment: International Clinical Evaluation of Rituximab in RA) trial, a phase IIb study undertaken to examine the efficacy and safety of rituximab at two doses, with or without glucocorticoids (GCs), in patients with active rheumatoid arthritis (RA) resistant to disease-modifying anti-rheumatic drugs (DMARDs), including biologic agents. Patients were randomized to receive either placebo infusions or rituximab at a dose of 500 mg or 1 g on days 1 and 15, together with one of three glucocorticoid options: glucocorticoid placebo, 100 mg intravenous methylprednisolone before each rituximab infusion, or 100 mg methylprednisolone before each infusion in addition to an oral corticosteroid. Pre-treatment with methylprednisolone before rituximab infusion reduced the incidence and severity of reactions by about one-third. IV, Intravenous. *(Data from Emery P, Fleischmann R, Filipowicz-Sosnowska A; DANCER study group , et al: The efficacy and safety of rituximab in patients with active rheumatoid arthritis despite methotrexate treatment: results of a phase IIB randomized, double-blind, placebo-controlled, dose-ranging study.* Arthritis Rheum *54:1390–1400, 2006.)*

characterized as mild or moderate. The reactions included hypotension, hypertension, flushing, pruritus, and rash. In the rare case of severe reactions, it has been suggested that a cytokine release syndrome associated with marked cell lysis after rituximab might be a contributing factor.

In summary, the findings of the phase IIa study indicated that a single course of treatment with rituximab, particularly in combination with methotrexate, produces an enduring response in patients with severe, seropositive, active RA. Further, treatment with rituximab was well tolerated, with a favorable safety profile over 48 weeks of follow-up.

To follow up the phase IIa study, a phase IIb study was undertaken to examine the efficacy and safety of rituximab at different doses, with or without glucocorticoids, in patients with active RA who were resistant to disease-modifying anti-rheumatic drugs (DMARDs), including biologic agents. The findings of this phase IIb study, known as the DANCER (Dose-ranging Assessment: International Clinical Evaluation of Rituximab in RA) trial, have been reported.[24] A total of 465 persons with active disease were recruited. To be included in the study, they had to have (1) failed to respond to at least one DMARD other than methotrexate, but no more than five, or failed to respond to biologic response modifiers, and (2) been treated with methotrexate as a single DMARD for at least 12 weeks, with 4 weeks of stable therapy at a dose of at least 10 mg a week. All other DMARDs were withdrawn at least 4 weeks before randomization—8 weeks for infliximab, adalimumab, and leflunomide. Patients were randomized to receive either placebo infusions or rituximab at a dose of 500 mg or 1 g on days 1 and 15, together with one of three glucocorticoid options: glucocorticoid placebo, 100 mg of intravenous methylprednisolone before each rituximab infusion, or 100 mg of methylprednisolone before each infusion in addition to an oral corticosteroid.

The results at 24 weeks confirmed the significant efficacy of a single course of rituximab in active RA when combined with methotrexate. This benefit was independent of glucocorticoids, although administration of methylprednisolone on day 1 reduced the incidence and severity of first rituximab infusion reactions by about one-third (Figure 64-2). Both rituximab doses were efficacious. At the lower dose, 55% of recipients achieved ACR20 responses, as did 54% of those at the higher rituximab dose—in both cases, significantly greater than the 28% of the subjects who received placebo infusions. Similarly, significantly higher proportions of subjects achieved ACR50, ACR70 (see Table 64-1), and European League against Rheumatism (EULAR) good responses at 24 weeks at both rituximab doses compared with subjects who received placebo infusions (Figure 64-3). At the most stringent ACR70 response level, the difference in the percentage of responders in the placebo, lower-dose rituximab, and higher-dose rituximab groups was most marked at the higher rituximab dose of 1 g 2 weeks apart (5%, 13%, and 20%, respectively; $P < 0.05$). Adverse events reported up to 24 weeks were largely infusion related, particularly at the time of the first infusion.

A trial known as REFLEX (Randomized Evaluation of Long-term Efficacy of Rituximab in RA) was designed to determine the efficacy and safety of rituximab when used in combination with methotrexate in patients with active RA who have had an inadequate response to one or more anti-TNF therapies because of either lack of efficacy (90% of patients recruited) or toxicity (10% of patients recruited); in addition, all patients had radiographic evidence of at least one joint with definite erosion attributable to RA

(Figure 64-4). The recruited cohort consisted of 520 patients with a mean disease duration of 12 years with a background regimen of methotrexate, 10 to 25 mg once a week. After a washout period during which other DMARDs and anti-TNF drugs were withdrawn, patients were randomized to receive a single course of 1 g of rituximab or placebo infusions on days 1 and 15. All patients were given 100 mg of intravenous methylprednisolone before each infusion and a brief course of oral prednisolone between the two doses: 60 mg daily from days 2 to 7, and 30 mg daily from days 8 to 14.[25]

Of the patients assigned to receive rituximab, 82% completed 6 months, compared with only 54% of the patients assigned to receive a placebo. The major reason for study withdrawal was lack of response, reported in 40% of the placebo group and 12% of the rituximab group. At 6 months, significantly more patients receiving rituximab achieved ACR20, ACR50, and ACR70 responses than did those receiving placebo: 51%, 27%, and 12%, respectively, of subjects receiving rituximab, versus 18%, 5%, and 1%, respectively, of those receiving placebo (see Table 64-1). In terms of change in Disease Activity Scale (DAS28), intention-to-treat analyses showed that in patients who received placebo infusions, the reduction from baseline was 0.34, which was less than the 0.6-point reduction considered to be clinically meaningful; in contrast, the reduction was 1.83 in the rituximab group.[25]

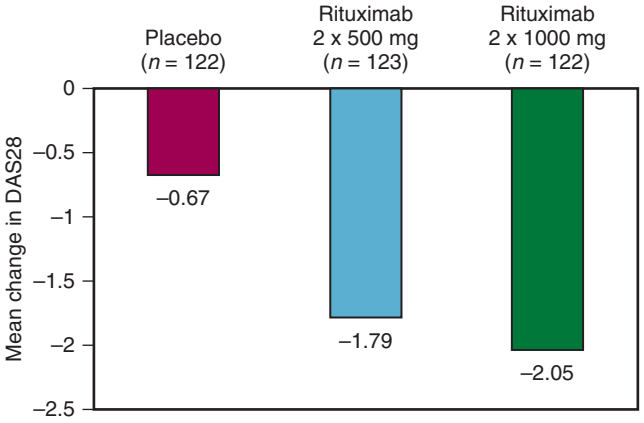

**Figure 64-3** DANCER (Dose-ranging Assessment: International Clinical Evaluation of Rituximab in RA trial) changes in the Disease Activity Scale (DAS)28 at 6 months. Mean changes in DAS28 from baseline in the phase IIb DANCER study were significantly greater in patients treated with two rituximab infusions 2 weeks apart at either 500 mg or 1 g each, compared with placebo infusions ($P < 0.0001$). *(Data from Emery P, Fleischmann R, Filipowicz-Sosnowska A; DANCER study group, et al: The efficacy and safety of rituximab in patients with active rheumatoid arthritis despite methotrexate treatment: results of a phase IIB randomized, double-blind, placebo-controlled, dose-ranging study.* Arthritis Rheum *54:1390–1400, 2006.)*

The ACR response evaluates RA treatment based on a 20%, 50%, or 70% improvement in five of seven core components. However, from the patient's perspective, determining the actual benefit of an ACR20 improvement is not straightforward. In the REFLEX study, the rituximab group had significantly greater improvements in all components of the ACR core measures. Rituximab demonstrated a clinically meaningful benefit for patients with RA in physical function as evaluated by a Health Assessment Questionnaire (HAQ) in all non-overlapping ACR response categories. In the active treatment arm, both clinical and subjective parameters of the ACR core components contributed to the assignment of an ACR20 response, whereas in the placebo group, the subjective parameters dominated.[25]

In the REFLEX study, after a single treatment course, the maximal clinical response to rituximab plus methotrexate was observed at 24 weeks. After this time, patients were eligible to exit the study and receive further rituximab treatment based on clinical need. Of the patients in the rituximab plus methotrexate group, 37% (114 of 308) remained in the study over 48 weeks, indicating continued clinical benefit after the single initial treatment course. The majority of patients who withdrew did so to receive further courses of rituximab between weeks 24 and 48 of the study. In contrast, 89% of the placebo plus methotrexate group (185 of 209) withdrew before week 48.[26]

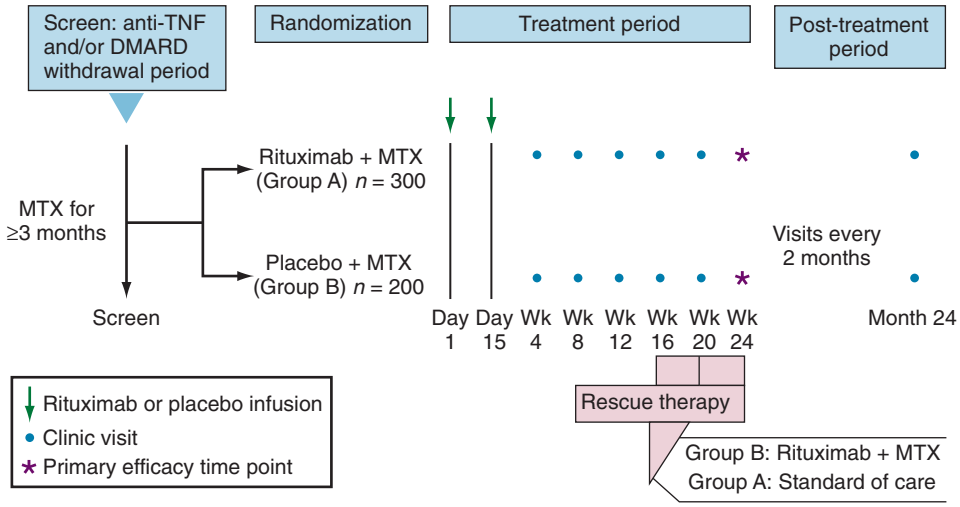

**Figure 64-4** The design of the phase III REFLEX (Randomized Evaluation of Long-term Efficacy of Rituximab in RA) study to determine the efficacy and safety of rituximab when used in combination with methotrexate (MTX) in patients with active rheumatoid arthritis (RA) who have an inadequate response to one or more anti–tumor necrosis factor (TNF) therapies. DMARD, Disease-modifying anti-rheumatic drug.

Another phase III study, known as SERENE (Study Evaluating Rituximab's Efficacy in methotrexate iNadequate rEsponders), confirmed the benefits of rituximab in patients with RA receiving concomitant methotrexate who had active disease at baseline despite methotrexate therapy and who had not received prior biologic therapy.[27] Patients were randomized to receive either placebo or rituximab at one of two doses, 2 × 500 mg or 2 × 1000. From week 24, in an open-label extension, the patients in the rituximab arms who did not achieve remission as assessed by DAS28 received a second course of rituximab, and all patients who had received placebo were treated with the lower rituximab dose. At week 24, a significantly greater proportion of patients receiving rituximab, 2 × 500 mg or 2 × 1000 mg plus methotrexate, achieved the primary endpoint of an ACR20 response versus patients receiving placebo plus methotrexate (54.5% and 50.6% vs. 23.3%, respectively; $P < 0.0001$). By week 48, approximately 90% of patients in all treatment groups had received a second course of treatment. The majority of these repeat treatments (82% to 88%) were given by week 30.

In patients treated with rituximab, efficacy outcomes at week 48 were comparable with those at week 24; additionally, improvement was observed for several clinically important endpoints, including an approximate doubling in the proportion of patients who achieved low disease activity (DAS28 < 3.2) in the rituximab (2 × 1000 mg) plus methotrexate–dose group from week 24 to week 48. The safety profile of rituximab in the SERENE study was comparable with that observed in earlier trials, with the most common adverse event being infusion-related reactions, most of which were not serious, at the time of first infusion. Reductions in immunoglobulin levels were observed, predominantly IgM, but with mean levels remaining within normal limits. No relationships between infectious complications and reduced immunoglobulin levels were observed—in fact, the rate of infection observed in patients receiving rituximab plus methotrexate was low and comparable with that of patients receiving methotrexate alone over the placebo-controlled 24-week period. This low rate of serious infection continued throughout the full 48-week period, with no obvious difference between the rituximab doses.

Results from the IMAGE (International Study in Methotrexate-naïve Subjects Investigating Rituximab's Efficacy) study, which included 748 patients without prior use of either biologic drugs or methotrexate, have been reported. In this group, high-risk patients who had baseline high DAS28 scores or high C-reactive protein (CRP) levels were found to have greater DAS28 improvement at week 52 if they received rituximab in addition to methotrexate.[28]

## Disease Modification

**KEY POINT**

**Rituximab given as two infusions of 1 g each slows radiographic progression in patients with RA.**

The extraordinary success of TNF blockade in inhibiting structural damage to joints in patients with RA has set a new standard to which all new biologic agents must aspire. Inhibition of structural joint damage by rituximab in persons with RA and a previous inadequate response to TNF inhibitors from the REFLEX study was first described over a 1-year period,[29] with a subsequent demonstration that the initial effects of rituximab are maintained over an extended interval of 2 years, with all measures of joint damage significantly improved compared with placebo plus methotrexate.[30] At week 56,[29] the mean change in Genant-modified Sharp score in the placebo plus methotrexate arm was 2.31, compared with 1.0 in the rituximab plus methotrexate group ($P = 0.0043$). Significant differences were also reported for joint space narrowing and bone erosions. At week 104, significantly lower changes in total Genant-modified Sharp score (1.14 vs. 2.81; $P < 0.0001$), erosion score (0.72 vs. 1.80; $P < 0.0001$), and joint space narrowing scores (0.42 vs. 1.00; $P < 0.0009$) were observed with rituximab plus methotrexate versus placebo plus methotrexate.[30] Importantly, within the rituximab group, 87% who had no progression of joint damage at 1 year remained nonprogressive at 2 years. Thus these data confirm that treatment with rituximab plus methotrexate has the benefit of sustained inhibition of joint damage progression in patients with RA who had a previously inadequate response to TNF inhibitors.

Radiographic outcomes were reported for a phase III study designed to determine the efficacy of rituximab in the prevention of joint damage and its safety in combination with methotrexate in the context of patients initiating treatment with methotrexate.[28] This study, known as the IMAGE trial, was a randomized, controlled, double-blind trial involving 748 methotrexate-naïve patients assigned to receive rituximab at doses of either 2 × 1000 mg or 2 × 500 mg every 24 weeks in combination with methotrexate or methotrexate alone. The primary endpoint was radiographic progression measured by modified total Sharp score (mTSS) at week 52. In subjects treated with 2 × 1000 mg rituximab and methotrexate, a significantly smaller change (0.359) in the mTSS was observed compared with subjects taking methotrexate alone (1.079; $P < 0.001$). Furthermore, a significantly higher proportion of subjects treated with MabThera and methotrexate had no progression in their joint damage over 1 year (64% vs. 53%; $P = 0.0309$). By week 52, 65% of these subjects experienced a 50% improvement in symptoms (ACR50) and 47% experienced a 70% improvement (ACR70), compared with 42% and 25%, respectively, for subjects taking methotrexate alone ($P < 0.0001$ for both ACR50 and ACR70 comparisons).

Recent evidence suggests that rituximab inhibits joint damage independently of its effects on disease activity.[31] A random 90% sample of patient data from two arms of the IMAGE trial were divided into low, moderate, or high disease activity at 1 year of treatment by simplified disease activity index, or by swollen joint count or CRP tertiles. Progression of damage by the Genant mTSS was compared between therapies (Kruskal-Wallis and Wilcoxon tests) for each of these subgroups. In subjects treated with methotrexate, 1-year radiographic progression in low, moderate, and high disease activity was 0.40 ± 0.88, 1.04 ± 1.73, and 1.31 ± 3.02, respectively. In contrast, in subjects receiving rituximab plus methotrexate, radiographic progression was 0.38 ± 1.07, 0.39 ± 1.28 ($P = 0.003$ by comparison with methotrexate), and –0.05 ± 0.44 ($P = 0.05$ by comparison with

methotrexate), respectively. These data suggest that, as in the case of biologic TNF and interleukin-6 receptor (IL-6R) inhibition, anti-CD20 antibody conveys profound antidestructive effects and dissociates the link between disease activity and joint damage.

## Safety Issues

**KEY POINTS**

**Rituximab has an acceptable safety record in RA trials, but infusion reactions of variable severity can occur; most are mild to moderate. The frequency and severity of infusion reactions are reduced by the administration of intravenous methylprednisolone before rituximab infusions.**

**A very rare complication in patients with RA who are treated with rituximab is progressive multifocal leukoencephalopathy. Because of the increase in relative risk, patients should be counseled appropriately.**

The rapidity and magnitude of peripheral blood B cell depletion after anti-CD20 therapy raises concerns about potential adverse sequelae. The peripheral compartment recovers after many months, but repopulation occurs predominantly with an immature and naïve subset of B cells. However, it must also be remembered that the circulation contains less than 2% of total B cells.[32] A common concern regarding all therapies directed at B cells is the potential for toxicity related to modulation of humoral immunity. Unlike other newly introduced biologic therapies for RA, rituximab has the considerable advantage of an oncology safety database based on more than 350,000 treatments of patients with non-Hodgkin's lymphoma since 1997.[33] The overall safety conclusions are that serious adverse events are infrequent and often associated with well-defined risk factors such as cardiopulmonary disease or a high number of circulating cancer cells. Of note, in the lymphoma population, prolonged peripheral B cell depletion has not been associated with cumulative toxicity or increased occurrence of opportunist infections.[34-36] However, it cannot be assumed that the toxicity profile will be identical in distinct disease phenotypes with differing pathogenic processes.

In RA open-label,[37] phase II,[23,24] and phase III[21] studies, although decreases in total serum immunoglobulin levels were observed in patients receiving rituximab, concentrations remained within normal limits. Of note, existing antibody titers against tetanus toxoid appear to be unaffected by a single course of rituximab treatment.[38] However, some anecdotal evidence indicates that total serum immunoglobulin concentrations fall below the normal range in patients receiving multiple cycles of rituximab treatment over a number of years in open-label studies.[11] It is unclear whether this outcome results in an increased risk of infection. In phase II studies, the majority of adverse events, including headache, nausea, and rigors, were mild to moderate and were associated with infusions. In a meta-analysis of randomized clinical trial data from three studies that reported adverse events arising after a single cycle of rituximab treatment in a total of 938 patients with RA who were refractory to nonbiologic DMARDs or biologic anti-TNFs,[23-25] it was calculated that the incidence of patients experiencing adverse events of all systems was not higher in the patients treated with rituximab than in the placebo groups (relative risk [RR], 1.062; 95% confidence interval [CI], 0.912 to 1.236; $P = 0.438$).[39]

In the DANCER trial, adverse events associated with rituximab were largely associated with the first infusion; these adverse events occurred in 39% of subjects treated with 500 mg of rituximab (without use of a steroid) and in 46% receiving 1 g, compared with 17% in subjects who received placebo infusions.[24] The corresponding incidence with the second infusion decreased to 5%, 8%, and 10%, respectively. Two serious infusion reactions, hypersensitivity and generalized edema, occurred on day 1. Pre-treatment with methylprednisolone reduced the incidence and severity of reactions by about one-third (see Figure 64-2). Infectious adverse events (largely upper respiratory tract infections) were reported in 28% of subjects who received a placebo and in 35% of subjects who received rituximab. Six serious infections occurred: two in the placebo group, four in patients receiving 1000 mg of rituximab, and none in patients receiving 500 mg of rituximab. No opportunistic infections or tuberculosis reactivations were reported.

Although the overall safety record based on trial data has been favorable, with wider clinical use of biologic B cell depletion, rarer serious complications have come to light. A potential association has been reported between the biologic therapies efalizumab, natalizumab, and rituximab and the rare, progressive, and usually fatal condition termed progressive multifocal leukoencephalopathy (PML), a rare brain disease caused by reactivation of the John Cunningham (JC) virus.[40] PML has been reported in patients receiving rituximab for hematologic conditions and systemic lupus erythematosus (SLE)[41] and, more recently, in patients with RA.[40] The cumulative incidence rate of PML in the RA population has been estimated at 1/100,000 RA admissions in an analysis limited to hospitalized patients with SLE and other rheumatic diseases (including 25 patients with RA), a majority of whom had concomitant risk factors, including HIV, malignancy, or transplantation of bone marrow or another organ.[42] The cumulative reporting rate of 2.2 cases of PML per 100,000 patients with RA treated with rituximab is more than double the estimated frequency in RA (95% CI, 0.3 to 8.0).[40] Although the absolute risk is small, the RR is such that it emphasizes the importance of providing the prospective patient being considered for B cell–depleting therapy, with thoughtful and balanced information about likely benefits, as well as more common through very rare complications.

The profound and enduring peripheral B cell depletion that accompanies use of rituximab raises a potential safety concern for patients in clinical practice who fail to derive adequate symptomatic benefit and may then be exposed to biologic DMARDs of an alternative mechanism of action at a time point before repopulation of circulating B cells can take place. Relatively few data regarding this circumstance are available to date, but preliminary information is available in 185 of 2578 patients with RA who went on to receive a biologic agent with an alternative mechanism of action as documented in a safety follow-up period after participation in trials in which they had previously received rituximab.[43] Of the 185 patients, 89% remained depleted of peripheral B cells at the point of beginning treatment with

a biologic agent with a new mechanism of action. The rate of serious infectious events reported after treatment with rituximab but prior to the second biologic exposure was 6.99 per 100 patient-years, which is comparable with the reported rate of 5.49 per 100 patient-years after exposure to a second biologic agent, the majority of which were TNF inhibitors. No fatal or opportunistic infections were observed, with the nature and course of infectious complications being within expectations for patients with RA receiving biologic therapy. In a population of methotrexate-naïve patients entering the IMAGE study,[28] safety data were consistent with results from previous rituximab clinical trials and further enhance the robust safety profile. Rates of serious adverse events and serious infections were similar between the two MabThera groups and the methotrexate-only group.

Persons with RA, particularly those treated with immunosuppressants, are at an increased risk of infection, and for this reason, vaccination is an important aspect of RA clinical management. The question of whether B cell–depleting therapy could adversely affect immunization responses by suppressing the antibody response from new vaccination or reducing pre-formed antibody from prior vaccination has been investigated, and the findings have been reported.[44-46] These studies indicate that vaccine responses to some, but not all, vaccinations may be diminished in patients treated with rituximab, most strikingly in the first 4 to 8 weeks after administration of rituximab.[44] Although prior vaccination and timing of vaccine administration after rituximab infusion may influence the ability to mount a response, no straightforward relationship exists between peripheral B cell reconstitution and response to immunization. Therefore, when vaccination is indicated, ideally it should be performed prior to rituximab treatment and avoided immediately after B cell depletion with a delay of several months. Of course, this guideline may not be practical for vaccines with seasonal availability (such as those for influenza variants), and it must be recognized that responses to vaccination do not necessarily correlate with the risk of infection. In general, the timing of rituximab administration must be determined according to clinical need without the requirement to delay until after supplies of a seasonally variable vaccine become available and the patient has been immunized.

In a recent meta-analysis of 6 studies enrolling 2728 patients, nonmelanotic skin carcinoma occurred more commonly than other carcinomas in the rituximab treatment groups (0.8% in the rituximab group vs. none reported in the control group). Moreover, the overall incidence of malignancies was higher in the rituximab group (2.1%) compared with the control group (0.6%).[47]

The safety and efficacy profile of rituximab in the treatment of RA discussed thus far is based on reports from randomized placebo-controlled trials of 6 to 12 months' duration. Open-label extension studies have analyzed safety and efficacy results over multiple courses of rituximab.[48] In safety analyses based on 5013 patient-years of rituximab exposure, in a total of 2578 patients with RA who received at least one course of rituximab, infusion-related reactions were the most common adverse event occurring in a quarter of patients during the first infusion of the initial treatment cycle, although only 1% of infusion reactions in total were considered to be of a serious nature. Importantly and reassuringly, the rates of both adverse events and serious adverse events were stable over infusion cycles, with the latter reported as 17.85 events/100 patient-years (95% CI, 16.72 to 19.06). Infections and serious infections over time remained stable across five treatment cycles at four to six events/100 patient-years. No cases of tuberculosis, disseminated fungal infections, or other serious opportunistic infections were identified during the analysis period.

Viral reactivation is a potential concern in immunosuppressed patients. The rate of herpes zoster infections in this large series was 0.98 events per 100 patient-years, similar to that reported for other RA populations. The much more serious and rare opportunistic infection PML occurred in a single patient who also received cancer chemotherapy and radiation, with the event occurring about 18 months after the last dose of rituximab and 9 months after receiving chemotherapy and radiation. The causal relationship to rituximab, if any, is thus not entirely clear. There was no increased risk of malignancy by comparison with reference patients with RA and with the general population in the United States. Myocardial infarction was one of the most common serious adverse events reported in the longer-term analyses at a rate of 0.56 per 100 patient-years, but this is consistent with rates reported in epidemiologic studies of patients with RA.

## Duration of Benefit

**KEY POINT**

**Repeat treatment with rituximab produces clinical responses that equal or exceed those from the first course of treatment, with a comparable duration of effect.**

Among patients with RA who experience clinical responses to rituximab treatment, the time to clinical relapse is heterogeneous. In some patients, relapse is closely correlated to the reappearance of peripheral blood B cells, but in other patients, it may be delayed by years.[49] Clinical relapse is more closely associated with increases in autoantibody levels, but better biomarkers are needed to reliably inform optimal management strategies on an individual basis. All B cell populations are depleted after rituximab therapy. Of residual B lineage cells, more than 80% exhibit a memory or plasma cell precursor phenotype.[50] B cell repopulation occurs at a mean of 8 months after rituximab therapy and depends on the formation of naïve B cells of an immature phenotype resembling those found in umbilical cord blood. Peripheral B cell depletion is accompanied by substantial increases in blood BLyS concentrations, which tend to fall with B cell repopulation.[51] BLyS is a naturally occurring protein required for the development of B lymphocytes into mature plasma cells. Elevated levels of BLyS in persons with RA are believed to contribute to the production of autoantibodies. However, in cases of prolonged clinical responses to rituximab, more gradual reductions in BLyS concentrations have been observed, extending beyond the period of B cell depletion. Thus BLyS may contribute to the survival or regeneration of pathogenic, autoreactive B cells. This hypothesis predicts a potential therapeutic role for BLyS blockade in addition to B cell depletion.

Information concerning the efficacy and safety of repeated cycles of rituximab treatment has emerged from experience in clinical practice and from randomized trials. The recently reported phase III MIRROR (Methotrexate Inadequate Responders Randomised study Of Rituximab) trial was a randomized, double-blind, international study to evaluate the efficacy and safety of three dosing regimens of rituximab in combination with methotrexate in 375 patients with active RA and an inadequate response to methotrexate.[52] Patients were randomized to three groups with two courses of rituximab treatment at varying doses as follows: group A: 500 mg rituximab (all courses) on days 1 and 15, with repeat treatment at 24 weeks; group B: first course 500 mg rituximab on days 1 and 15, a second course of 1000 mg of rituximab, and repeat treatment at 24 weeks; and group C: 1000 mg of rituximab (all courses) on days 1 and 15, with repeat treatment at 24 weeks. The primary endpoint was the proportion of patients achieving ACR20 at week 48. Secondary endpoints included ACR50, ACR70, and EULAR responses. There was a trend toward better efficacy results with the regular 2 × 1000-mg dose compared with the low dose of 2 × 500 mg, and this reached statistical significance for EULAR good/moderate response (2 × 1000 mg = 88% vs. 2 × 500 mg = 72%, $P < 0.05$). Other endpoints, although numerically superior at 48 weeks, did not show any statistically significant difference between the three dosing regimens.

## Current Role

**KEY POINT**

**Rituximab is generally considered to be an effective biologic option in patients with RA, particularly seropositive patients who have inadequate responses to TNF inhibitors.**

Recent advances in our understanding of the pathogenesis of RA emphasize the critical role of B cells in self-sustaining chronic inflammatory processes. Rituximab is an important addition to the therapeutic armamentarium for the treatment of RA. In current clinical practice, the major use for rituximab in the treatment of RA is confined to the TNF inhibitor–refractory population. SWITCH-RA is a global, observational study comparing the effectiveness of rituximab versus an alternative TNF inhibitor in patients with RA who had an inadequate response to one previous anti-TNF agent.[53] In this large cohort, 604 patients received rituximab and 507 received an alternative anti-TNF as a second biologic therapy. Reasons for discontinuing the first anti-TNF were inefficacy, intolerance, and other. Least squares mean (SE) change in DAS28-3-erythrocyte sedimentation rate (ESR) at 6 months was significantly greater in patients who received rituximab than in patients who received an anti-TNF agent: −1.5 versus −1.1; $P = 0.007$. The difference remained significant among patients who discontinued the initial anti-TNF agent because of inefficacy (−1.7 vs. −1.3; $P = 0.017$) but not because of intolerance (−0.7 vs. −0.7; $P = 0.894$). Seropositive patients showed significantly greater improvements in DAS28-3-ESR with rituximab than with an anti-TNF agent (−1.6 vs. −1.2; $P = 0.011$), particularly those who switched because of inefficacy (−1.9 vs. −1.5; $P = 0.021$). The overall incidence of adverse events was similar between the rituximab and TNF inhibitor groups. These real-life data suggest that particularly in seropositive patients and in patients who switched because of inefficacy after discontinuation of an initial TNF inhibitor, switching to rituximab is associated with significantly improved clinical effectiveness compared with switching to a second anti-TNF agent.

Data from a number of clinical trials (IMAGE, MIRROR, SERENE, REFLEX, and DANCER)[24,27,28,52,54] suggest that seropositive patients with RA (RF and/or ACPA) show a higher likelihood of response to B cell–depleting therapy compared with seronegative patients, in particular for improving signs and symptoms and inhibition of radiographic changes. However, it is nevertheless the case in both trials and clinical experience that a proportion of seronegative patients with RA show good clinical responses, although this proportion is less than in the case of seropositive patients.[55] In pooled analyses of data from the MIRROR and SERENE studies, at week 48, odds ratios for seropositive patients versus seronegative patients of achieving ACR20, ACR50, and ACR70 responses were 2.23 (95% CI, 1.38 to 3.58), 2.72 (95% CI, 1.58 to 4.70), and 3.29 (95% CI, 1.40 to 7.82), respectively.[56] These observations generate the hypothesis that other mechanisms may account for lower levels of response in seronegative patients, such as antigen presentation, co-stimulation, and cytokine drive, whereas high levels of response to rituximab therapy may be mediated primarily by the suppression of pathogenic antibodies. In contrast to RF, the type I IFN signature has been shown to be associated with a negative response to rituximab therapy in patients with RA.[57]

The optimal and most cost-effective dosing regimen for rituximab remains a matter of debate. The phase III SERENE study showed equal clinical efficacy for the 500 mg × 2 and 1000 mg × 2 rituximab doses,[27] but the phase III MIRROR trial[52] had differences in some outcomes favoring the higher dosage. Methotrexate-naïve patients (not an approved patient population for rituximab) were studied in the IMAGE study with clinical results that were equivalent, but with a radiographic result that favored the higher dosage.[28] Thus a summary of the current randomized controlled trial (RCT) data on rituximab dosing is that 1000 mg × 2 works well in a clinically meaningful proportion of patients, but not in all patients. The 500 mg × 2 rituximab dose achieves broadly similar results in the relevant patient populations overall and has the advantages of lower cost and possibly a lower rate of serious adverse events but perhaps with lower probability of high-impact clinical responses and inhibition of structural damage. Based on the DANCER study findings, it is recommended that each cycle of 1000 mg × 2 rituximab be given in combination with once-weekly methotrexate, usually at doses of at least 15 mg/week, to optimize efficacy. Further, administration of 100 mg intravenous methylprednisolone is recommended before each rituximab infusion to reduce the frequency and severity of infusion reactions.

Rituximab may also have a role in patients for whom TNF blockade is relatively contraindicated, such as those with connective tissue disease overlap syndromes. At present, uncertainties exist about the implications of long-term peripheral B cell depletion and the timing and need for redosing with rituximab in patients who respond.

Current research suggests that restoration of peripheral B cell numbers takes about 8 months after depletion treatment, although retreatment may be needed earlier. Results have been presented for an open-label study to evaluate the response to repeated courses of rituximab in patients with active RA who are participating in one of several phase II or III studies and to determine the optimal frequency for repeated treatment.[58] In a series of 155 patients with prior exposure to TNF inhibitors, ACR20, ACR50, and ACR70 scores were 65%, 33%, and 12%, respectively, after the first course, and they were 72%, 42%, and 21%, respectively, for the second treatment course, relative to the original baseline. In 82 of these patients who received a third course of rituximab, the median interval between the first and second courses was very similar to that between the second and third courses: 30 to 31 weeks.[58] Further studies are needed to identify the optimal regimens for maintenance therapy that will provide efficacy and limit toxicity.[59] Development of biomarkers informative of management decisions that would optimize response is a highly desirable goal, but as yet no biomarkers are in routine use. The magnitude of clinical response appears to be related to the completeness of peripheral B cell depletion, and this holds true whether the lower 500 mg × 2 dose schedule or the higher 1000 mg × 2 schedule is administered. By means of sensitive measurements permitting detection of very low numbers of preplasma B cells in the circulation, a recent study reported that patients with RA whose disease did not respond to an initial cycle of rituximab have higher circulating preplasma cell numbers at baseline and incomplete depletion. Furthermore, an additional cycle of rituximab administered prior to total B cell repopulation enhances B cell depletion and clinical responses.[60]

Although the available safety data for rituximab in persons with RA are reassuring, these data need to be interpreted with caution until larger numbers of patients have been treated and long-term safety and retreatment data become available. Further, a substantial body of safety data for rituximab in the treatment of non-Hodgkin's lymphoma is available, with similarly low infection rates reported. In oncology, some of the associated adverse events are related to circulating tumor loads. Overall, these data are reassuring with regard to the RA population, although close monitoring of immunocompetence and for the possibility of rare opportunistic infections is advisable.

## Future Directions and Other Approaches to B Cell–Targeted Therapy

**KEY POINT**

**Additional biologic approaches that target B cells are under investigation.**

Rituximab is currently indicated for the treatment of patients with moderate to severe RA who show no response, experience a loss of response with time, or have adverse effects to anti-TNF agents.[61] The findings of recently reported studies indicate that rituximab is also efficacious in a proportion of both patients with RA who are treatment naïve and patients with RA who take methotrexate, particularly if they are seropositive.[27,28] Therefore, in the face of competitive health economic data compared with TNF inhibitors, there has been interest in the potential of rituximab as a first-line biologic agent. However, questions remain about the safety of repeated treatment cycles, although encouraging data are emerging. Although the U.S. Food and Drug Administration (FDA) has received reports of patients who experienced fatal PML after rituximab treatment for SLE and RA, this event appears to be rare. A key issue that determines the future place of B cell depletion therapy will be defining the most effective strategy in early stages of RA to induce a remission and potentially even biologic-free remission, whether this can be achieved safely and effectively with rituximab, and whether any biomarkers can be developed that will reliably inform biologic treatment strategy on an individual patient basis.

Clinical trials and safety data for other antibodies targeting CD20, such as ocrelizumab, a humanized version of rituximab, and ofatumumab, a fully human anti-CD20, have also been reported. In phase I/II trials in persons with RA, ocrelizumab, in combination with methotrexate, was found to be safe and effective at doses consisting of two infusions of 200 mg or higher given 2 weeks apart.[62] Two ocrelizumab dose levels were studied in three phase III RA studies across various patient populations; full findings have yet to be reported. However, in spring 2010, a decision was announced to discontinue development of ocrelizumab for the RA indication after a detailed analysis of the efficacy and safety data from the RA program found that the overall benefit-risk profile of ocrelizumab was not favorable, taking into account other currently available treatment options. This decision was based on an infection-related safety signal that included serious infections, some of which were fatal, and opportunistic infections.

Ofatumumab is a human IgG1κ lytic monoclonal antibody with specificity for human CD20 antigen. It recognizes a unique membrane-proximal epitope on the human CD20 molecule that is distinct from the epitope recognized by rituximab and ocrelizumab.[63] The membrane proximity of this epitope is likely to account for the high efficiency of B cell killing observed with ofatumumab in both in vitro and in vivo pre-clinical studies. A phase I/II study of ofatumumab, administered as two intravenous infusions of 300, 700, or 1000 mg 2 weeks apart in patients with active RA who had an inadequate response to DMARDs, demonstrated significant clinical benefit and reasonable tolerability (which improved after implementation of pre-medication) at all doses investigated when compared with placebo, with the 700-mg dose considered optimal.[63] Despite these positive results in RA studies, further work on ofatumumab by intravenous delivery in autoimmune conditions was discontinued, and focus on a subcutaneous delivery program began. Plans for a study in persons with multiple sclerosis are under way, but further development in RA remains under review, although this situation has not been prompted by the observation of unexpected opportunist infections as was the case for ocrelizumab.

Many other approaches to B cell–targeted therapy are in clinical testing, although it is unlikely that any of these will have a significant impact on the rituximab niche in the near future. Alternative strategies to target the B cell compartment include the use of BLyS antibodies. Belimumab is a

human anti-BLyS monoclonal antibody recently investigated in clinical trials for the treatment of RA and other rheumatic indications. An alternative approach to BLyS inhibition that is still in the early stages of clinical development is to block signaling through BLyS receptors using a soluble receptor, such as transmembrane activator and calcium modulator and cyclophilin ligand interactor immunoglobulin. Preliminary results of a phase II double-blind, placebo-controlled study of belimumab in active RA have been presented.[64] Patients were randomized to receive intravenous belimumab at a dose of 1, 4, or 10 mg/kg or placebo infusions on days 0, 14, and 28, then every 28 days through 24 weeks. The ACR20 response at week 24 in the combined belimumab groups was 29%, compared with 16% in the placebo group; no dose response was observed. The antibody was well tolerated. These preliminary findings with a functional inhibitor of B cells are surprising, given the effectiveness of rituximab; however, it may simply represent a pharmacokinetic problem, indicating that the dose of belimumab was too low. The benefit-risk ratio of belimumab has come under close scrutiny by the FDA, and it seems unlikely that it will progress in clinical development with RA as an indication.

## RITUXIMAB IN OTHER RHEUMATIC CONDITIONS

**KEY POINT**

**Rituximab has demonstrated benefits in studies of RA and anti-neutrophil cytoplasmic antibody–associated vasculitis. Clinical trials in SLE have not shown clinical benefit.**

Rituximab has also been used to treat a number of other rheumatic diseases.[11] Theoretical considerations and preliminary data suggested that B cell depletion using rituximab might have efficacy for immune thrombocytopenia, anti-neutrophil cytoplasmic antibody (ANCA)–associated vasculitis, and SLE. The rationale for the use of rituximab in the treatment of patients with ANCA-associated vasculitis is that elimination of CD20 B cell precursors could lead to transient removal of pathogenic antibodies and remission, assuming that ANCA are produced by short-lived B lineage cells rather than long-living plasma cells. Furthermore, in ANCA-associated vasculitis, the number of activated, circulating B lymphocytes correlates with disease activity and tissue involvement. Therefore the hypothesis that rituximab might induce disease remission in patients with severe ANCA-associated vasculitis has been tested in a phase II/III multicenter, randomized, double-blind, placebo-controlled trial known as RAVE (Rituximab for ANCA-associated Vasculitis). Findings have been reported comparing rituximab (375 mg/m$^2$ administered intravenously once weekly for 4 weeks) with cyclophosphamide (2 mg/kg/day administered orally).[65] Sixty-three patients in the rituximab group (64%) reached the primary endpoint, compared with 52 patients in the control group (53%), a result that met the criterion for noninferiority ($P < 0.001$). The rituximab-based regimen was more efficacious than the cyclophosphamide-based regimen for inducing remission of relapsing disease; 34 of 51 patients in the rituximab group (67%) compared with 21 of 50 patients in the control group (42%) reached the primary endpoint ($P = 0.01$). Rituximab was also as effective as cyclophosphamide in the treatment of patients with major renal disease or alveolar hemorrhage. No significant differences were found between the treatment groups with respect to rates of adverse events. Despite these encouraging data, the true positive effect of rituximab in ANCA-associated vasculitis is difficult to determine because of the simultaneous administration of high-dose glucocorticoids, which may contribute to a substantial decrease in ANCA titers and the observed remission rates.

Given the large body of evidence implicating abnormalities in the B cell compartment in SLE, a recent therapeutic focus has been to develop interventions that target the B cell compartment by multiple mechanisms, and rituximab has been studied most extensively. The best evidence in support of using rituximab for the treatment of patients with ANCA-associated vasculitis or SLE comes from clinical experience, retrospective case series, and small prospective uncontrolled studies, mainly in patients with refractory or frequently relapsing disease.[66,67] However, very recently, two moderately sized phase III randomized placebo-controlled trials of rituximab for the treatment of moderately active nonrenal SLE (EXPLORER) or class III/IV lupus nephritis (LUNAR) have failed to demonstrate superiority of this B cell–depleting agent compared with placebo when added to standard of care, that is, conventional immunosuppressive therapy. Both trials had a relatively short follow-up period. Preliminary data from LUNAR (a study to evaluate the efficacy and safety of rituximab in subjects with International Society of Nephrology/Renal Pathology Society [ISN/RPS] class III or IV lupus nephritis) have been reported.[68] This multicenter, randomized, double-blind, placebo-controlled trial included 144 patients with lupus nephritis (67% of patients had class IV disease) and compared the efficacy and safety of rituximab with placebo. Patients with class III and IV disease and a urine protein to creatinine ratio greater than 1 were randomly assigned to receive either 1000 mg of rituximab or placebo on days 1, 15, 168, and 182, in conjunction with mycophenolate mofetil and corticosteroids. No significant differences were observed in complete or partial renal response or clinical benefit to therapy at week 52, although rituximab administration was associated with significantly reduced titers of antibodies to double-stranded DNA and increased levels of C3 complement component. Serious adverse events, such as infection, were similar between the two patient groups.

The EXPLORER trial (a study to evaluate the efficacy and safety of rituximab in patients with severe SLE) randomly assigned patients with SLE who had moderate to severe disease activity despite treatment with immunosuppressive agents and corticosteroids to receive either placebo or rituximab infusions.[69] Patients with active glomerulonephritis were excluded. The British Isles lupus assessment group index was used to score treatment response four times per week for 52 weeks after the first infusion. Responses were recorded in 66% of patients in the placebo group and 75.1% of patients treated with rituximab. The time to the first moderate or severe flare did not differ between groups, but a trend for a prolonged time to the first "a" score flare in the rituximab group was observed. Annual rates of severe

and moderate disease activity flares were similar, but the mean annual rate of "a" score flares was significantly lower in the rituximab group than in the placebo group (0.86 vs. 1.41). The number of adverse events and overall infections were comparable between groups at 78 weeks, although serious infections were more numerous in the placebo group.

It is unclear why the LUNAR and EXPLORER studies failed to prove the superiority of rituximab to placebo in patients with SLE, although design flaws seem likely. Overuse of concomitant steroids and continued immunosuppressive treatment could help mask the possible benefits of rituximab. Moreover, consensus is lacking regarding the optimal dose and administration regimen of rituximab in patients with SLE and adjustments for the organ or system involved. EXPLORER included patients with very active disease who were treated aggressively with moderate-to high-dose glucocorticoids, which made the short-term detection of treatment benefits difficult.[70] Other potential shortcomings for lupus clinical studies in general, including EXPLORER and LUNAR, is that the length of follow-up may have been too short to demonstrate separation between the different treatments. The unexpected failure to show overall clinical benefit of rituximab in SLE trials may also reflect the inadequacy of the clinical outcome instruments employed. This factor is less likely to be relevant in the LUNAR nephritis study, for which the outcome measurements were more unequivocal. It is noteworthy that in both the EXPLORER and LUNAR studies, outcomes appeared to be more favorable in African-American and Hispanic subjects.[71]

Rituximab has also been used in primary Sjögren's syndrome; granulomatosis with polyangiitis; hepatitis C–associated cryoglobulinemia; ANCA-associated vasculitides other than granulomatosis with polyangiitis, such as polyarteritis nodosa, dermatomyositis, and polymyositis[72]; antiphospholipid syndrome; and scleroderma.[73]

## TARGETING CO-STIMULATORY MOLECULES

**KEY POINT**

**Activated T cells are implicated in the pathogenesis of RA, and co-stimulation is essential in induction of adaptive immune responses.**

Co-stimulation is an essential step in the induction of adaptive immune responses. Although the role of T cells in the perpetuation of RA has been debated and remains poorly understood, it has long been believed that T cell activation is a key event in the pathogenesis. Successful T cell activation requires multiple signals. One signal is provided by presentation of an antigen bound to cell surface major histocompatibility complex (MHC) molecules on antigen-presenting cells to a specific T cell receptor (TCR). In the absence of further signals, T cells become unresponsive and may ultimately be eliminated through apoptosis. An important co-stimulatory signal is provided by an interaction between members of the B7 family (either CD80 or CD86) on antigen-presenting cells and CD28 on T cells (Figure 64-5). Other key interactions between antigen-presenting cells and T cells are mediated by the binding of intercellular adhesion molecule-1 (ICAM-1) to leukocyte function-associated antigen-1 (LFA-1), CD40 to CD40 ligand, LFA-3 to CD2, and so on. After activation, T cells express cytolytic T lymphocyte–associated protein 4 (CTLA-4), which interferes with the B7-CD28 interaction and helps return the cells to the quiescent state.

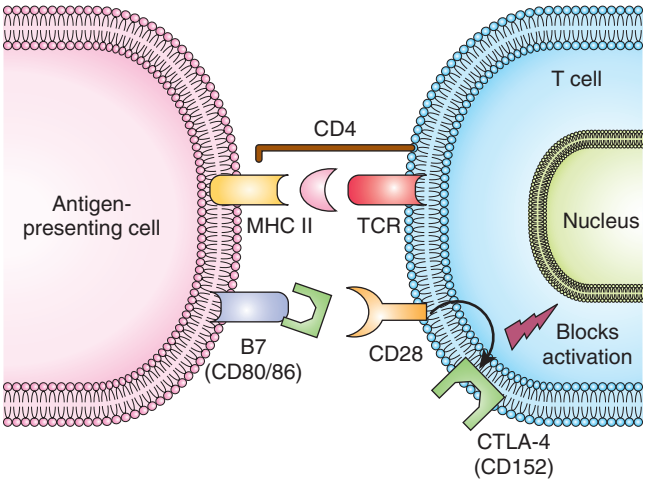

**Figure 64-5** Interactions between antigen-presenting cells and T cells. Successful T cell activation requires multiple signals. One signal is provided by the presentation of an antigen bound to cell surface major histocompatibility complex (MHC) molecules on antigen-presenting cells to a specific T cell receptor (TCR). In the absence of further signals, T cells become unresponsive and may ultimately be eliminated through apoptosis. An important co-stimulatory signal is provided by an interaction between members of the B7 family (either CD80 or CD86) on antigen-presenting cells and CD28 on T cells. After activation, T cells express cytolytic T lymphocyte–associated protein 4 (CTLA-4), which interferes with the B7-CD28 interaction and helps return the cells to the quiescent state.

## ABATACEPT AND RHEUMATOID ARTHRITIS

**KEY POINT**

**Abatacept is a human fusion protein comprising the extra-cellular portion of CTLA-4 and the Fc fragment of IgG-1.**

Abatacept is a novel, fully human fusion protein consisting of the extra-cellular portion of CTLA-4 and the Fc fragment of human IgG-1 (CTLA-4Ig). In December 2005, abatacept (Orencia) became the first co-stimulatory blocker to be approved by the FDA for the treatment of patients with RA who have had an inadequate response to other drugs. Abatacept binds to CD80 and CD86 on antigen-presenting cells, thus preventing these molecules from binding their ligand, CD28, on T cells, with the consequent inhibition of optimal T cell activation. In vitro, abatacept decreases T cell proliferation and inhibits the production of TNF, IFN-γ, and IL-2. CTLA-4Ig showed promising activity in rodent collagen-induced arthritis models, prompting its evaluation in several clinical trials in persons with RA.[74,75]

## Clinical Studies

**KEY POINT**

**Abatacept is an effective therapy across the spectrum of RA patient populations. For a majority of patients achieving clinical responses in the first 6 months, sustained clinical responses follow that may be incremental for up to 2 years of treatment.**

Abatacept has been evaluated in several double-blind, placebo-controlled trials in a number of clinical scenarios in adults with active RA. These scenarios include an inadequate response to conventional DMARDs such as methotrexate or to TNF inhibitors and, more recently, methotrexate-naïve patients in the early phase of disease. In addition, data have been reported in the context of an exploratory phase II study designed to assess the effect of co-stimulation blockade on progression of undifferentiated, early inflammatory arthritis to fulfill classification criteria for RA.

An initial 3-month, phase IIa, double-blind, randomized, placebo-controlled pilot study demonstrated the efficacy of B7 blockade in treating the signs and symptoms in patients with active RA despite treatment with at least one conventional DMARD.[76] In this pilot study, the effect of one of two different biologic co-stimulatory modulators was compared with that of placebo infusions. The two biologic agents used were CTLA-4Ig, which binds approximately fourfold less avidly to CD86 than to CD80, and belatacept, a second-generation CTLA-4Ig with two mutated amino acid residues conferring an increased avidity for CD86 over that of the parent molecule. The proportion of patients achieving ACR20 responses on day 85 was dose dependent, suggesting clinical efficacy for both co-stimulatory blocking molecules.

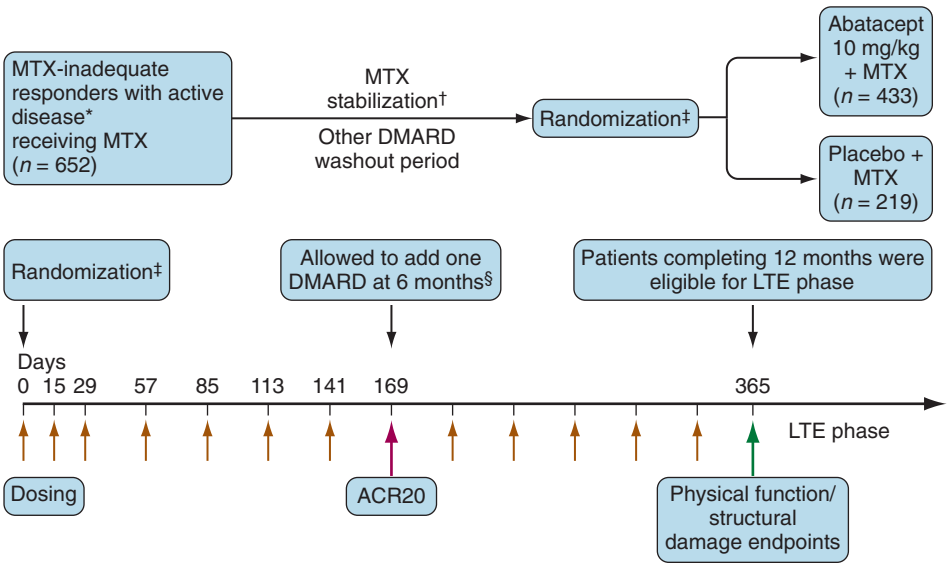
The findings were confirmed in a multicenter phase IIb study of abatacept plus methotrexate in 339 patients who had active RA despite methotrexate treatment.[77] In this study, patients were randomized to receive infusions of placebo; abatacept, 2 mg/kg; or abatacept, 10 mg/kg at baseline, at 2 weeks, 4 weeks, and then monthly through 6 months. ACR20 responses were achieved in 60%, 41.9%, and 35.3% of patients receiving the 10-mg/kg dose of abatacept, the 2-mg/kg dose of abatacept, and placebo, respectively. At the more stringent ACR50 response level, the figures were 36.5%, 22.9%, and 11.8% (Table 64-2). Improvements in the individual components of the ACR response criteria were generally greater in the 10-mg/kg group than in the 2-mg/kg group. No deaths, malignancies, or opportunistic infections were reported for any patient receiving abatacept during the 6 months of therapy. Patients in the phase IIb study continued to receive blinded therapy for an additional 6 months, during which time response to therapy was maintained. For patients receiving 10 mg/kg of abatacept, the ACR70, ACR50, and ASCR20 response rates were 21%, 42%, and 63%, respectively, compared with 8%, 20%, and 36% for patients receiving placebo infusions. Further, at the higher dose, statistically significant improvements in physical function and health-related quality of life were maintained over the 1-year period.[78] In the phase IIb study, from day 90 onward, statistically significant and progressively rising differences in remission rates were observed between the group receiving methotrexate plus abatacept, 10 mg/kg, and the group assigned to methotrexate and placebo infusions. By 1 year of treatment, 34.8% of patients receiving abatacept plus methotrexate achieved a DAS28 remission (<2.6), in contrast to 10.1% of the patients receiving methotrexate plus placebo ($P < 0.001$).[78] Patients completing the double-blind phase over 12 months became eligible to enter a long-term extension phase in which all participants received methotrexate plus abatacept, 10 mg/kg. At year 3, patients treated with abatacept experienced greater than 70% improvement in swollen and tender joint counts and approximately 50% improvement in pain and physical function.[79] Patients who received placebo infusions during the double-blinded phase and then switched to abatacept during the long-term extension rapidly achieved equivalent efficacy to those treated with abatacept throughout.

**TABLE 64-2** Percentage of Patients Achieving Responses at 24 Weeks in the AIM and ATTAIN Studies

| Study | Drug Regimen | ACR20 | ACR50 | ACR70 |
|---|---|---|---|---|
| Phase IIb AIM[42] | Abatacept 10 mg/kg + methotrexate | 60 | 37 | 17 |
| | Methotrexate | 35 | 12 | 2 |
| Phase III AIM[45] | Abatacept 10 mg/kg + methotrexate | 68 | 40 | 20 |
| | Methotrexate | 40 | 17 | 7 |
| Phase III ATTAIN[46] | Abatacept 10 mg/kg + methotrexate | 50 | 20 | 10 |
| | Methotrexate | 20 | 4 | 1 |

ACR, American College of Rheumatology; AIM, Abatacept in Inadequate Responders to Methotrexate; ATTAIN, Abatacept Trial in Treatment of Anti-TNF Inadequate Responders.

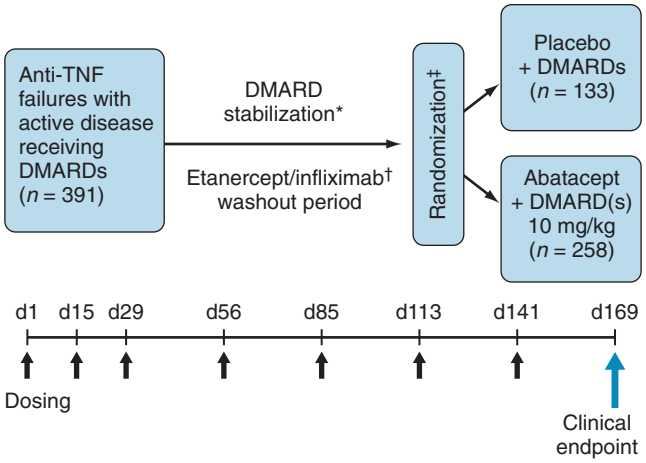
The findings of two large phase III studies of abatacept in different RA populations have been reported. A population of methotrexate-refractory patients was studied in the Abatacept in Inadequate Responders to Methotrexate (AIM) trial. This study was designed to further evaluate the safety and clinical efficacy of abatacept plus methotrexate, as well as the effect on radiographic progression.[80] In the other phase III study, the Abatacept Trial in Treatment of Anti-TNF Inadequate Responders (ATTAIN),[81] the objective was to determine whether abatacept is a safe and effective treatment for patients with RA who were unresponsive to previous anti-TNF treatment.



In the AIM study, 652 patients with RA who had an inadequate response to methotrexate were randomly assigned to receive placebo or a fixed dose of abatacept approximating 10 mg/kg on days 1, 15, and 29 and every 4 weeks thereafter for a year; all patients continued to receive background methotrexate therapy.[80] Both patient groups exhibited high disease activity at baseline, with a DAS28 of 6.4. Patients receiving abatacept showed greater improvement in all ACR response criteria at 6 and 12 months than did patients treated with placebo (see Table 64-2). In findings similar to the phase IIb study, abatacept plus methotrexate-induced DAS28 remission (<2.6) in 14.8% of patients at 6 months and in 23.8% at 12 months, compared

with 2.8% and 1.9% of patients receiving methotrexate plus placebo at the corresponding time points ($P < 0.001$). Physical function significantly improved in 63.7% of the abatacept plus methotrexate group, versus 39.3% of the placebo plus methotrexate group ($P < 0.001$). Further, patients taking the abatacept and methotrexate combination had a slower progression of mean structural damage (1.2 mTSS points over 1 year) compared with methotrexate alone (2.3 mTSS points).[80] Of interest, when assessed by conventional clinical outcome measures such as EULAR response, the data suggest that a plateau of clinical efficacy is achieved with abatacept between 4 and 6 months of treatment. However, using more stringent measures for analyses, such as time to a low DAS (DAS28 < 3.2) or time to a sustained low DAS, no plateau of efficacy was observed over the first 12 months, suggesting an ongoing recruitment of clinical benefit with abatacept plus methotrexate.[82]

Patients completing the double-blind phase of the AIM study over 12 months became eligible to enter a long-term extension phase in which all participants received methotrexate plus abatacept at a fixed dose approximating 10 mg/kg every 4 weeks (Figure 64-6). Clinically meaningful reductions in disease activity were maintained through 2 years, accompanied by an improved sense of subjective well-being assessed by patient-reported outcomes.[83] Further, inhibition of structural damage to joints was sustained, as evaluated by plain radiography; the effect after 2 years of abatacept was significantly greater than that at 1 year, with minimal radiographic progression observed over the second year of treatment.[84]



A third trial in methotrexate-inadequate responders provided the opportunity to evaluate two biologic agents in a single study. The placebo- and active comparator-controlled ATTEST (abatacept or infliximab versus placebo, a trial for tolerability, efficacy, and safety in treating RA) study, although not powered to detect superiority, provided information on the relative efficacy and safety profiles of abatacept and infliximab versus placebo in the same population.[85] Patients with an inadequate response to methotrexate were randomized (3:3:2) to abatacept (approved dose), infliximab (3 mg/week) or placebo with background methotrexate. At month 6, patients in the placebo group were switched to abatacept, and infliximab and abatacept groups continued to year 1, with blinding maintained. The primary endpoint of this trial, reduction in DAS28 (ESR) at month 6 for abatacept versus placebo, was met, with mean reductions of −2.53 versus −1.48 ($P < 0.001$), respectively. The proportion of patients achieving low disease activity and DAS28 remission was also greater with abatacept. Improvements in ACR20, ACR50, and ACR70 responses at month 6 were significantly greater versus placebo for both abatacept and infliximab. The onset of ACR20 responses was generally more rapid for infliximab than for abatacept, but responses were similar by month 3. By year 1, DAS28 (ESR) reductions of −2.88 and −2.25 were seen for patients treated with abatacept and infliximab, respectively, and ACR responses were maintained from month 6 with abatacept but not with infliximab.

In the ATTAIN phase III study, abatacept therapy was evaluated in 391 patients with active disease receiving conventional DMARDs or anakinra who failed to respond adequately to at least 3 months of therapy with etanercept, infliximab, or both agents at the approved doses.[81] Anti-TNF therapy was discontinued at the time of enrollment if it had not been stopped previously. After a washout period, patients were randomly assigned in a 2:1 ratio to receive

*≥10 swollen joints (66 joint count), ≥12 tender joints (68-joint count) and CRP ≥ 1.0 mg/dL and ≥3 months on MTX ≥ 15 mg/wk.

**TABLE 64-3** Comparison of TNF Inhibition Versus Other Biologics Abatacept versus Adalimumab (AMPLE trial)

| Treatment Regimen | Total Number of patients | Number of patients showing MTX-inadequate response | Percentage of patients showing MTX-inadequate response |
|---|---|---|---|
| SC Abatacept + MTX | 318 | 206 | 64.8 |
| Adalimumab + MTX | 328 | 208 | 63.4 |

Estimate of difference (95% CI) between groups was 1.8 (-5.6, 9.2); Intent to treat, confirmed with per protocol population

MTX, Methotrexate.

Modified from Weinblatt ME, et al: Head-to-head comparison of subcutaneous abatacept versus adalimumab for rheumatoid arthritis: findings of a phase IIIb, multinational, prospective, randomized study. *Arthritis Rheum* 65(1):28–38, 2013.

either the same fixed dose of abatacept (approximating 10 mg/kg) or placebo (Figure 64-7). Patients receiving abatacept showed significantly greater improvement in all ACR response criteria through 6 months (see Table 64-2) than did patients treated with placebo (ACR20 response 50.4% vs. 19.5%, $P < 0.001$; ACR50 response 20.3% vs. 3.8%, $P < 0.001$; and ACR70 response 10.2% vs. 1.5%, $P = 0.003$) (Table 64-3). Further, a DAS28 remission was achieved in 10% of patients receiving abatacept versus only 1% of patients receiving placebo infusions plus DMARDs. ACR20 responses were seen irrespective of whether patients had previously been exposed to etanercept, infliximab, or both anti-TNF therapies without an adequate response. Improvement in physical function was also significantly increased in the abatacept group (47% vs. 23%). The incidence of infection was slightly higher in the abatacept group than in the placebo group, although no specific infection was clearly more frequent, and the intensity of infections was similar in the two groups. There were no significant differences in the number of patients discontinuing treatment as a result of infection or in the incidence of serious infection.

All patients who completed the 6-month double-blind phase of the ATTAIN study were eligible to enter a 1-year, long-term extension phase during which all patients received a once-monthly fixed dose of abatacept in addition to at least one conventional DMARD.[86] Of 258 patients randomized to receive abatacept during the double-blind phase, 223 completed 6 months of treatment, and 218 entered the long-term extension. Of these patients, 168 completed 18 months of treatment. The ACR20 responses observed at the end of the double-blind phase were sustained throughout the 1-year extension phase, with the proportion of patients achieving the more stringent ACR50 and ACR70 responses rising to 35% and 18%, respectively, at 18 months. Further, the proportion of patients meeting DAS28 remission criteria doubled to 22.5% by the end of the extension period. Similarly, among all patients initially treated with abatacept and DMARDs who entered the long-term extension phase, the mean reduction in DAS28 from baseline to the end of the double-blind phase was –1.99; by the end of 18 months, the mean reduction from baseline was –2.81. In the double-blind phase, patients assigned to placebo infusions together with DMARDs had a mean reduction in DAS28 of –0.93; at the end of the long-term extension, after crossing over to abatacept infusions, the reduction from baseline was –2.72.[87] These data again emphasize the sustained but relatively slow and incremental clinical responses observed after abatacept therapy.

The second trial conducted in TNF-inadequate responders was a phase IIIb/IV, 6-month, open-label study. The ARRIVE (Abatacept Researched in Rheumatoid arthritis patients with an Inadequate anti-TNF response to Validate Effectiveness) trial was the first to assess the safety of abatacept in patients who switched directly from TNF antagonist therapy without undergoing washout, an approach that may be more clinically relevant for everyday practice.[88] Patients enrolled in this study had high disease activity levels at entry and an inadequate response to up to three TNF antagonists; the inadequate response could have occurred for efficacy, safety, or tolerability reasons. Patients were eligible even if they had a positive purified protein-derivative test result. Abatacept could be administered as monotherapy (for those recruited in the United States only), and patients were not limited to a particular background DMARD. Similar, clinically meaningful improvements were seen in disease activity, physical function, and health-related quality of life, regardless of whether there was a washout period. Post hoc analyses revealed that, numerically, more patients who had previously failed to respond to one TNF antagonist achieved DAS28-defined remission and low disease activity than did those who had failed to respond to two or more TNF inhibitors.

Because T cell activation is believed to be an initiating event in an immunologic cascade observed in RA, co-stimulation blockade might be predicted to have benefits from an early stage of evolution of the syndrome independently of any driving antigen or antigens. The 2-year abatacept study to gauge remission and joint damage progression

in methotrexate-naïve patients with early erosive RA (AGREE) consisted of a 12-month double-blind period, followed by a 12-month open-label period in methotrexate-naïve patients with early RA.[89] Eligibility included short disease duration, poor prognostic factors, including high CRP levels, radiographic evidence of erosions, and seropositivity for RF or ACPA. Patients were randomized 1:1 to receive abatacept plus methotrexate ($n = 256$) or methotrexate alone ($n = 253$) during the first 12-month period.[89] From year 1 onward, all patients received open-label abatacept plus methotrexate. The co-primary endpoints were 28-joint DAS (DAS28)-defined remission and radiographic joint damage progression at year 1.

Significantly more patients treated with abatacept plus methotrexate achieved DAS28 (CRP)-defined remission and ACR50 and ACR70 responses at year 1, and the difference between treatment arms was significant by month 2. Over 1 year, 27.3 versus 11.9% of patients treated with abatacept plus methotrexate versus patients treated with methotrexate alone ($P < 0.001$) experienced a major clinical response (ACR70 maintained for 56 consecutive months).[89] Significant improvements were also seen in physical function at year 1 for patients treated with abatacept plus methotrexate compared with patients treated with methotrexate alone.[89] Improvements in disease activity and ACR responses were sustained or improved over the second year for patients who continued to receive abatacept plus methotrexate therapy, with 55.2% achieving remission at year 2.[90] Changes from baseline to year 1 in Genant-mTSS and erosion score were significantly lower for methotrexate-naïve patients who were randomized to the abatacept plus methotrexate arm.[89] Furthermore, there was an increasing degree of inhibition of progression in year 2 relative to year 1 for patients originally randomized to the abatacept arm.[91] For patients originally receiving methotrexate alone, structural damage progression was reduced over year 2 relative to year 1, following the addition of abatacept.[90] However, overall structural damage progression at year 2 remained greater for these patients compared with patients who received abatacept from baseline.[90]

The potential for early treatment with abatacept to delay the time of progression to fulfillment of classification criteria for RA in persons with ACPA-positive, undifferentiated, early inflammatory arthritis with clinical synovitis of two or more joints was investigated in an exploratory, phase II, 2-year study known as ADJUST (abatacept study to determine the effectiveness in preventing the development of RA in patients with undifferentiated inflammatory arthritis).[92] After 6 months of double-blind, randomized (1:1) treatment with either abatacept at the approved dose of approximately 10 mg/kg ($n = 28$) or placebo ($n = 28$), abatacept treatment was terminated. At year 1, the proportion of patients who developed RA according to ACR 1987 criteria or discontinued because of lack of efficacy was assessed. When treatment with abatacept was stopped after 6 months, 22 and 17 patients treated with abatacept and placebo, respectively, remained in the study inasmuch as they had not fulfilled classification criteria for RA; by year 2, 7 and 4 patients treated with abatacept and placebo, respectively, remained in the study. Numerically, RA developed in more patients treated with placebo than in those treated with abatacept over 1 year (66.7% vs. 46.2%), although CIs overlapped. Radiographic assessments demonstrated an inhibitory effect on structural damage progression at month 6, which was maintained for 6 months after therapy cessation, with similar trends observed for MRI-assessed osteitis, erosion, and synovitis.[92] Abatacept treatment was also associated with reductions in ACPA levels that persisted beyond cessation of the active drug. At enrollment, patients had short symptom duration, and although they did not meet ACR 1987 criteria for RA at the point of recruitment, more than half already had evidence of one or more erosions and were thus likely to have had early RA. The findings must be interpreted in light of this situation.

The popularity among patients of the subcutaneous delivery route out of available choices of parenteral delivery has prompted studies to look at effectiveness and safety of subcutaneously delivered abatacept, which is now available in a subcutaneous formulation, consisting of a fixed dose of 125 mg of the drug, administered once weekly. Six clinical trials have been performed in patients with RA treated with the subcutaneous formulation, including ACQUIRE (a phase II dose-finding study comparing the efficacy of intravenous and subcutaneous formulations),[93] ALLOW (withdrawal-restart study of immunogenicity with subcutaneous abatacept plus methotrexate vs. methotrexate),[94] ACCOMPANY (a study of immunogenicity in subcutaneous abatacept plus methotrexate vs. subcutaneous abatacept),[95] ATTUNE (intravenous to subcutaneous switch study),[96] and AMPLE (head-to-head subcutaneous abatacept plus methotrexate vs. adalimumab plus methotrexate).[97] All of these studies demonstrate an efficacy and a safety profile comparable with that obtained with the classic intravenous administration. In particular, it has been demonstrated that the fixed dose of the drug achieves a serum concentration comparable with that reached with the weight-tiered intravenous regimen, eliciting therapeutic concentrations in more than 90% of patients.

The AMPLE trial (abatacept versus adalimumab comparison in biologic-naïve subjects with RA with background methotrexate) in particular deserves further elaboration. In a noninferiority phase III study design, AMPLE was the first head-to-head study in patients with RA that was powered to compare biologic DMARD agents on a background of methotrexate in persons who were inadequate responders to methotrexate therapy and naïve to biologic DMARD therapy. Methotrexate-refractory persons with active RA who were naïve to biologic therapy were recruited. A total of 318 persons were randomized to weekly subcutaneous 125-mg doses of abatacept without an intravenous loading dose plus methotrexate with once-weekly placebo injections, and 328 persons were randomized to biweekly adalimumab plus methotrexate with once-weekly placebo injections. Because unmarked adalimumab (Humira) syringes could not be obtained, the study was single blinded, using a rigorous protocol, including a blinded assessor at each recruiting site.

The AMPLE trial demonstrated the comparable efficacy of subcutaneous abatacept to adalimumab on background methotrexate with respect to the primary outcome measure, ACR20 at 1 year, with subcutaneous abatacept demonstrating noninferiority to adalimumab (64.8% vs. 63.4%). Furthermore, comparable response and kinetics were seen across all efficacy measures, including ACR 20/50/70 and

DAS28 (CRP) responses, as well as inhibition of radiographic progression. Safety outcomes were balanced with some differences, namely, fewer discontinuations due to adverse events and serious adverse events in the subcutaneous abatacept group. Local injection site reaction complaints were also significantly less frequent in persons receiving subcutaneous abatacept. These findings confirm the clinical impression that among currently available biologic therapies, abatacept is at the better tolerated and safe end of the safety spectrum.

## Safety Issues

**KEY POINTS**

**Abatacept has acceptable safety across the spectrum of RA patient populations.**

**Abatacept is administered either as a 30-minute intravenous infusion that is usually without complications or as a once-weekly, fixed dose, subcutaneous injection that is tolerated with a very low rate of injection site reactions.**

Safety assessments from abatacept clinical trials have in general demonstrated a comparable overall incidence of adverse events and serious adverse events for persons treated with abatacept and placebo. The safety of long-term abatacept treatment is reported to be consistent, with the incidence of overall adverse events and serious adverse events remaining stable up to 7 years.[98]

A safety analysis has been undertaken on pooled data from abatacept clinical trials through December 2007 that included 4150 patients who were exposed to abatacept. This represents 10,365 patient-years of exposure, with an average exposure period of 2.5 years.[98] The incidence of serious infections was generally low, although it was higher for persons treated with abatacept compared with persons treated with placebo over 1 year (serious infections: 3.47 vs. 2.41 events/100 patient-years, respectively). Records of annual incidence rates for serious infections did not appear to show an increase in risk over time. Pneumonia, bronchitis, cellulitis, and urinary tract infection were the most common causes of hospital admission for infections. Opportunistic infections were rarely observed in this pooled cohort, including the following events per 100 patient-years of treatment: *Mycobacterium* tuberculosis, 0.06 events; aspergillosis, 0.02; blastomycosis, 0.01; and systemic *Candida*, 0.01.[98]

The incidence of malignancies (excluding nonmelanoma skin cancer) during the double-blind treatment periods was reported to be 0.59 events/100 patient-years for persons treated with abatacept versus 0.63 events/100 patient-years for persons treated with placebo. This low incidence rate did not rise with increasing exposure. In particular, for lung cancer and lymphoma, the incidence rate was 0.24 lung cancers and 0.06 lymphomas/100 patient-years during the double-blind period and 0.16 lung cancers and 0.07 lymphomas/100 patient-years during the cumulative period. To better interpret malignancy risk data, the incidence rates observed in abatacept studies were compared with those documented in five observational cohorts of patients with RA who were naïve to biologics and were taking nonbiologic DMARDs. Standardized incidence rates for the observational cohorts ranged from 0.4 to 1.06, and for patients treated with abatacept, the risk of lung cancer did not appear to be increased, with standardized incidence rates ranging from 0.65 to 1.84. The lymphoma risk in patients treated with abatacept appeared to be comparable with that in biologic naïve patients with RA, with standardized incidence rates ranging from 0.60 to 1.23.[98] In the pooled trial data from double-treatment periods, autoimmune events were reported in 1.4% of patients treated with abatacept and 0.8% of patients treated with placebo. Most events were mild or moderate in intensity, and the most frequently reported event was psoriasis, with rates of 0.53 and 0.56 events/100 patient-years over the double-blind and cumulative periods, respectively.

In clinical practice it is common to use conventional DMARDs in combination regimens, based on the belief that they provide additive benefits in terms of efficacy without the downside of unacceptable toxicity. Whether these same principles apply to the use of abatacept was addressed in the ASSURE trial (Abatacept Study of Safety in Use with other RA therapies).[99] This multicenter, randomized, double-blind study investigated the safety of adding abatacept or placebo infusions to a background treatment regimen of at least one of the traditional nonbiologic or biologic DMARDs currently approved for RA treatment for at least 3 months. A total of 1456 patients were randomized 2:1 to receive abatacept at a fixed dose approximating 10 mg/kg by weight range or placebo.

A number of interesting observations arose from this study. In the group as a whole, the proportion of serious adverse events occurring in each treatment arm was similar: 13% for abatacept and 12% for placebo. The discontinuations rate due to adverse events was 5% in the abatacept group and 4% in the placebo group. As expected on the basis of prior studies, serious infections occurred more frequently in the abatacept group (2.9%) than in the placebo group (1.9%). Five deaths occurred in the abatacept group and four deaths occurred in the placebo group; it was thought that all but one of the deaths in each group were unlikely to be related to the study drug. All the deaths occurred in patients without concomitant biologic background therapy. However, a subanalysis of the data, based on whether patients were receiving biologic or nonbiologic background therapy, revealed that serious adverse events occurred almost twice as frequently in the subgroup receiving abatacept plus another biologic agent (22.3%) as in the other subgroups (12.5%).

A particularly important observation in this study was the increased number of serious infections observed when abatacept was combined with other biologic therapies (5.8% vs. 1.6% for the subgroup receiving background biologic therapy plus placebo infusions). Further, the clinical benefits of abatacept tended to be less in the patients receiving background biologic therapy than in patients with a background of nonbiologic DMARDs. No cases of lymphoma, demyelinating disorders, or tuberculosis were reported.

The ASSURE trial findings mirrored those of a smaller randomized, placebo-controlled, double-blind pilot study. This phase IIb trial investigated the efficacy and safety of the addition of abatacept infusions at 2 mg/kg over 1 year

in patients with at least 8 of 66 swollen joints and 10 of 68 tender joints despite at least 3 months of treatment with twice-weekly 25-mg subcutaneous etanercept.[100] The biologic combination had limited clinical benefit compared with etanercept and placebo infusions but was associated with an increase in the proportion of patients experiencing serious adverse events (16.5% vs. 2.8%) and serious infections (3.5% vs. 0%). On the basis of these observations, the use of abatacept is not advised in combination with other biologic therapies.

Data are emerging concerning the comparative efficacy, safety, and kinetics of response for the anti-TNF antibody infliximab and abatacept.[101] In a 1-year double-blind study, patients with RA who had an inadequate response to methotrexate (a mean baseline DAS28 of 6.8) and no prior anti-TNF therapy were randomized to receive abatacept at a dose approximating 10 mg/kg every 4 weeks (156 patients); infliximab, 3 mg/kg every 8 weeks (165 patients); or placebo every 4 weeks (110 patients). Patients randomized to receive a placebo were switched to abatacept after 6 months but were not included in the 1-year analyses. At the end of the first 6 months, the frequency of serious adverse events was 5.1%, 11.5%, and 11.8% for abatacept, infliximab, and placebo, respectively. In the same order, the frequency of acute infusion-related adverse events was 5.1%, 18.2%, and 10%. Over the 1-year period, infections reported as serious adverse events were more frequent with infliximab (8.5%) than with abatacept (1.9%). These infections included two cases of tuberculosis, both in patients treated with infliximab. When considered in the light of the clinical response data discussed earlier, this study and others emphasize the relatively slow time to peak clinical response with abatacept in comparison with TNF blockade, with increasing efficacy beyond 6 months. These studies also point to the possibility of a favorable benefit-risk profile over 1 year. It will be critical to see whether these encouraging early safety data are maintained over the longer term.

Of note, the incidence rate of serious infections observed with abatacept is at the lower end of the range reported in patients with RA who are treated with other biologic agents. In summary, the long-term integrated safety data from up to eight abatacept trials, representing more than 10,000 patient-years of exposure, confirm that, overall, abatacept has a favorable safety profile that is consistent with observations from the short-term experience in all RA populations studied, with no new clinically important safety issues identified with long-term exposure. This conclusion is supported by a recent Cochrane review.[102]

## Current Role

**KEY POINT**

**Abatacept is a biologic option in patients with RA who have inadequate responses to TNF inhibitors, although recent evidence suggests that the benefit-risk profile of abatacept may be most optimal when introduced earlier in the treatment paradigm.**

Abatacept may be used as monotherapy or concomitantly with DMARDs other than TNF antagonists. It is not recommended for use concomitantly with IL-1 or TNF antagonists. The encouraging clinical trial data confirm that abatacept, like rituximab, represents a valuable agent in the therapeutic atramentarium for patients with RA who have not responded adequately to TNF blockade. Abatacept has a particular advantage among intravenously delivered biologics for RA in that it is very well tolerated and quick to administer, and infusion-related problems are rare. The more recently introduced subcutaneous formulation adds to the range of options for convenience of delivery depending on patient preference and circumstances. However, the clinical responses and radiographic benefits observed with abatacept appear to be greater in methotrexate-naïve patients compared with patients who have failed to respond to methotrexate or other DMARDs. Patients who previously failed to respond to methotrexate treatment appear to demonstrate higher clinical responses than patients who have failed to respond to TNF antagonists. Furthermore, the findings of the phase III AMPLE trial, which demonstrated noninferiority for efficacy with respect to symptoms and signs of abatacept plus methotrexate compared with adalimumab plus methotrexate, and comparable inhibition of structural damage progression, suggest that the most favorable clinical outcomes with abatacept may be achieved if it is used earlier in the treatment paradigm than was generally the case when it first became available for use in the clinic. Indeed, since the recent availability of the subcutaneous formulation, abatacept is increasingly finding favor as a well-tolerated and first-line choice of biologic therapy with a favorable benefit-risk ratio. The merits of switching a patient from a TNF inhibitor to abatacept or rituximab on the basis of a clinical response that is incomplete are not yet clear-cut with respect to disease modification. Other factors likely to inform the future use and relative positioning of biologics in the clinic include additional long-term safety data, comparative cost-effectiveness analyses, and the perceived convenience of intravenous versus subcutaneous administration.

## Implications for Understanding the Pathogenesis of Rheumatoid Arthritis

**KEY POINTS**

**The clinical efficacy of abatacept in persons with RA validates the importance of co-stimulation in the pathogenesis.**

**Co-stimulation inhibition modulates production of a number of pro-inflammatory cytokines.**

The clinical efficacy of abatacept in a proportion of patients with RA implicates co-stimulatory events in disease pathogenesis. However, abatacept might mediate immunosuppressive effects in RA by a number of different mechanisms. In the RA joint, blocking access of CD28 to CD80 or CD86 might be of little importance because memory T cells, which predominate in inflamed synovium, are much less dependent on this pathway.[103] A more important mechanism of action in the synovium might be the induction of tolerogenic antigen-presenting cells. Binding of CD80 or CD86 on antigen-presenting cells by CTLA-4Ig initiates a "reverse signal," with induction of tryptophan catabolism and inhibition of antigen presentation. Naïve T cells are

located predominantly in lymphoid tissue, and blockade of the CD28-CD80/CD86 interaction in lymph nodes may reduce T cell priming and the production of autoreactive T cells. Interestingly, patients with RA are reported to have higher frequencies of CD28-null T cells.[104] Further, the level of expression of CD28 is significantly reduced on all naïve T cells and memory $CD4^+$, $CD28^+$ T cells, a phenomenon related to overproduction of TNF.[105] A likely consequence of low-density cell surface expression of CD28 is that, for these T cells, abatacept can more readily block the interaction with CD80 and CD86.

The clinical and radiographic benefits of abatacept administration in persons with RA illustrate the importance of the co-stimulation pathway in T cell activation and subsequent amplification of the inflammatory cascade, including pathways that promote tissue destruction.[106] The modulatory effect of co-stimulation blockade on the expression of a range of inflammatory genes in synovial tissue has been demonstrated by quantitative PCR studies and evaluation of synovial biopsies in patients with active RA who received abatacept treatment, having previously failed to respond to TNF inhibitors.[107] Furthermore, a small, largely nonsignificant reduction in cellular content was observed in biopsy samples after abatacept treatment, suggesting that co-stimulation inhibition reduces the inflammatory status of the synovium without disrupting cellular homoeostasis.

## ABATACEPT IN OTHER RHEUMATIC CONDITIONS

**KEY POINTS**

**Abatacept has clinical use for treatment of RA and polyarticular juvenile idiopathic arthritis.**

**Clinical trials of abatacept in persons with psoriatic arthritis have shown benefit.**

In addition to the use of abatacept in the established phase of RA, abatacept in combination with methotrexate is indicated for the treatment of moderate to severe active polyarticular juvenile idiopathic arthritis in pediatric patients 6 years and older who have had an insufficient response to other DMARDs, including at least one TNF inhibitor. Results from a 12-month multicenter clinical trial did not show therapeutic benefit of abatacept over placebo in patients with non–life-threatening SLE. In particular, abatacept failed to prevent new disease flares in patients with SLE who underwent tapering of corticosteroids in an analysis where mild, moderate, and severe disease flares were evaluated together. Serious adverse events were higher in the abatacept group (19.8 vs. 6.8%). Although the primary and secondary endpoints were not met, improvements in certain exploratory measures were found.[108] Studies are ongoing in type 1 diabetes and inflammatory bowel disease.

Abatacept was also used in a 26-week, phase I, open-label, dose-escalation study of psoriasis vulgaris.[109] Sustained improvements of at least 50% in clinical disease activity were reported after four infusions of abatacept in 20 of 43 patients with stable psoriasis vulgaris. Clinical improvement was associated with quantitative reduction in epidermal hyperplasia, which correlated with a quantitative reduction in skin-infiltrating T cells. However, no clear-cut increase in the rate of intralesional T cell apoptosis was identified. It may be that the observed reduction in lesional T cells numbers was due to inhibition of T cell proliferation, T cell recruitment, or apoptosis of antigen-specific T cells at extralesional sites. Altered antibody responses to T cell–dependent neoantigens were observed, but immunologic tolerance to these antigens was not demonstrated. This study illustrates the importance of the CD28-CD152 pathway in the pathogenesis of psoriatic skin disease.

The findings of a 6-month, double-blind, placebo-controlled phase II trial in psoriatic arthritis have been reported.[110] The study included 170 adults meeting the Classification Criteria for Psoriatic Arthritis (CASPAR) with active arthritis (≥3 swollen joints and ≥3 tender joints), active plaque psoriasis (at least one qualifying target lesion ≥2 cm in diameter), and a disease duration of at least 3 months. All participants were required to have an inadequate response to DMARDs including, but not limited to, methotrexate or anti-TNF therapies. Persons who were either intolerant of or had an inadequate response to TNF inhibitors discontinued these therapies at screening and, after a washout period of greater than or equal to 28 days, were assessed for arthritis and psoriasis prior to randomization. Methotrexate was the only DMARD permitted to be continued at a stable dose during the study (in approximately 60% of participants). The participants were randomized to receive placebo or abatacept at a dose of 3 or 10 mg/kg or 30/10 mg/kg (i.e., two initial doses of 30 mg/kg, followed by a 10 mg/kg dose) on days 1, 15, 29 and then every 28 days. The primary endpoint was the ACR20 response at the end of 6 months. Key secondary endpoints included Investigator's Global Assessment (IGA) of psoriasis (ratings ranging from 1 [clear] to 4 [severe]), and the scores for the target lesion (based on the rating of skin erythema, induration, and scaling on a scale of 0 to 4 each), the HAQ Disability Index, and the Short Form (SF)-36 General Health Survey.

A total of 19%, 33%, 48%, and 42% of patients achieved an ACR20 with placebo or doses of abatacept of 3 mg/kg, 10 mg/kg, or 30/10 mg/kg, respectively. Compared with placebo, improvements were statistically significantly higher for the abatacept 10 mg/kg ($P = 0.006$) and 30/10 mg/kg ($P = 0.022$) dose groups, but not for the 3 mg/kg group ($P = 0.121$). An IGA response (i.e., a rating of psoriatic lesions as "clear or almost clear") was seen in 21% of the 30-/10-mg/kg dose group, 25% of the 10-mg/kg group, and 38% of the 3-mg/kg group; the latter was the only one that was statistically significantly different from placebo (26%; no statistical data presented). All doses of abatacept showed improvements in scores on MRI for joint erosion, osteitis, and synovitis; HAQ; and the SF-36. These encouraging early findings suggest that abatacept, at a dose of 10 mg/kg, may be a treatment option for patients with active psoriatic arthritis previously exposed to DMARDs, including anti-TNF therapies. Longer-term follow-up of these patients is ongoing, and further studies are planned.

In a small, open-label study, abatacept treatment was reported to be effective, safe, and well tolerated in patients with early and active primary Sjögren's syndrome, with treatment resulting in improved disease activity, laboratory parameters, fatigue, and health-related quality of life.[111] In

another small open-label study, 31 patients with RA and secondary Sjögren's syndrome completed 6 months of abatacept therapy. Eleven patients with histologic features characteristic of Sjögren's syndrome on a minor salivary gland biopsy had statistically significant improvements in saliva volume and in Schirmer's test for tear volume.[112]

## TARGETING T CELLS

### Clinical Studies

**KEY POINTS**

**A number of approaches to targeting T cells independently from co-stimulation pathways have not shown clear-cut benefit in clinical trials.**

In the early years of investigating the potential of biologic therapies in RA, T cells were among the first targets to be explored. Data from several different pre-clinical animal models of inflammatory arthritis suggested a pathogenic role for $CD4^+$ T cells in response to various arthritogenic antigens presented in the context of class II MHC molecules.[103] These observations led to a number of experimental protocols designed to investigate the effect of depleting and nondepleting antibodies directed at CD4, as well as other T cell–associated molecules. Early randomized, placebo-controlled clinical studies exploring the potential of biologic therapies targeting T cells in the treatment of RA have generally had disappointing results. Some anti–T cell agents were not efficacious; other preliminary trials demonstrating some clinical efficacy were terminated as a result of adverse events, particularly prolonged and profound T cell depletion.[113] However, the primatized monoclonal anti–CD4 antibody keliximab results in a dose-dependent clinical response when administered once weekly over 4 consecutive weeks, and the clinical response correlates with $CD4^+$ T cell coating with keliximab rather than T cell depletion. In two consecutive randomized, double-blind trials with comparable populations, keliximab treatment was associated with $CD4^+$ T cell counts below 250 cells/$mm^3$ in 12% of subjects in one study and in 47% of subjects in the other study.[114]

Examples of biologic therapies targeting other T cell–associated molecules include Campath-1H, a monoclonal antibody directed against CD52; a monoclonal anti–CD5 antibody linked to ricin toxin; and a fusion protein comprising an IL-2 receptor–binding domain coupled to diphtheria toxin ($DAB_{486}$IL-2 fusion toxin). CD52 is a polypeptide expressed on all lymphocytes. Campath-1H was tested as a treatment for refractory RA in two small trials, and although a single intravenous dose of between 1 and 100 mg resulted in significant $CD4^+$ T cell depletion and clinical improvement in more than half of patients, the correlation between biologic action and clinical response was poor.[115,116] Further, therapy was associated with significant acute toxicity, which was presumed to reflect a cytokine release syndrome, including headache, nausea, and hypotension. Arthritis activity returned over time despite prolonged suppression of peripheral blood $CD4^+$ T cell numbers.

CD5 is a transmembrane glycoprotein expressed on 70% of T cells. CD5-1C, a monoclonal antibody linked to ricin, a plant toxin that inhibits protein synthesis, was used to treat RA in a double-blind, placebo-controlled trial.[117] At the doses tested, only modest and transient T cell depletion was observed, and no clinical benefit occurred.

In a strategy designed to selectively deplete activated T cells expressing IL-2 receptor, $DAB_{486}$IL-2 fusion toxin was given by intravenous infusion in open-label and placebo-controlled studies.[118,119] Although a small percentage of patients (18%) exhibited clinical responses in the placebo-controlled study, the incidence of adverse events was significant, including nausea, fever, and raised plasma transaminases. Further, antibodies against diphtheria toxin developed in nearly all patients.

Other approaches to targeting T cells that have been tested include efforts to directly interfere with the trimolecular complex comprising human leukocyte antigen class II, antigenic peptide, and TCR by means of a DR4-DR1 peptide vaccine, TCR Vβ peptide vaccine, collagen, or cartilage glycoprotein 39.[120] Despite a rationale for these approaches based on promising pre-clinical animal model data, all have been abandoned because of borderline or absent clinical benefits in human disease.

## FUTURE DIRECTIONS

**KEY POINT**

**Novel approaches to targeting T cells are being tested, including T cell vaccination.**

The importance of immune regulation in maintenance of the healthy state is perhaps best illustrated by the consequences of immune dysregulation, a phenomenon common to a wide range of chronic inflammatory disease phenotypes. Emerging evidence points to the importance of certain $CD4^+$ T cell subsets in the negative regulation of the adaptive immune system. The best characterized of these subsets are the so-called naturally occurring $CD4^+CD25^+$ regulatory T cells and IL-10–producing Tr1 cells. Recent advances in the understanding of the molecular basis of $CD4^+CD25^+$ regulatory T cell generation include the observation that the X-linked forkhead–winged helix transcription factor Foxp3 is required for $CD4^+CD25^+$ T cell development and function. Although further progress in understanding the pathophysiologic role of regulatory T cells will require the identification of more specific markers for distinct regulatory T cell populations, there is already evidence of the feasibility of enhancing regulatory T cell function in vivo either by TCR modulation, using antibodies to CD3, or by co-stimulatory signals, using a CD28 superagonist.[121]

When a chronic inflammatory disease reflects an antigen-driven process, an attractive goal is to modulate T cell function in such a way as to generate antigen-specific unresponsiveness in the absence of long-term generalized immunosuppression. Some but not all studies report a relative deficiency of regulatory T cells in RA.[29] Of note, antibodies to CD3 and to TNF appear to enhance regulatory T cell function or number in patients with RA.[122-125] This finding raises the possibility that combination treatment with anti-CD3 and anti-TNF might be beneficial in more completely restoring immune regulation in persons with RA. In fact, chronic inflammation and overproduction of TNF perturb

T cell antigen receptor–dependent signaling,[126] suggesting that active inflammation may attenuate tolerogenic signals expected to be induced by a nondepleting anti-CD3 antibody. Thus pre-treatment with TNF blockade might restore tolerogenic signals transduced by the TCR in response to drugs such as anti-CD3. Although the use of anti-CD3 in the clinic has been limited by the occurrence of drug-induced cytokine release syndrome,[127] the effects can be modulated by anti-TNF agents, as demonstrated in patients treated for acute allograft rejection.[128] Such a combination therapy approach has yet to be tested in persons with RA.

A potentially beneficial immunomodulatory response has been demonstrated in a small open pilot study by vaccinating 16 patients with RA with expanded, activated, and irradiated autologous synovial fluid T cells.[129] Vaccination was associated with expansion of $CD4^+$ and $CD8^+$ T cells, many of which expressed the Vβ2 TCR chain. Some were anti-idiotypic, responding specifically to vaccine T cells with the production of IL-10 ($CD4^+$ cells) or granzyme B ($CD8^+$ cells). A broader regulatory response, however, was directed toward activated T cells in general, specifically against peptides derived from the IL-2 receptor α chain. This broader response may be important to generate in a syndrome such as RA, where the precise autoantigen and pathogenic T cell clones are not readily identifiable. This might also explain why earlier attempts at T cell vaccination using TCR-derived peptides have not been pursued.[120] However, the efficacy of such a T cell vaccination approach needs to be validated in further trials and the safety and durability of response must be further investigated before the potential feasibility of such an approach to therapy in routine clinical use can be properly assessed.

Anti–T cell therapies, including anti-CD4, cyclosporine, and CTLA-4Ig, synergize with TNF blockade in mice. Various agonists of immune inhibitory receptors on T cells could be potential adjuncts to anti-TNF, either without methotrexate or used together. The programmed cell death 1 (PD-1) protein, which is among the most potent inhibitory receptors on T cells, is responsible for the "exhausted" phenotype in chronic viral infection. PD-1 superagonists inhibit immune responses and upregulate regulatory T cells. Antibodies targeting PD-1 in persons with cancer have shown encouraging improvements in the context of advanced cancers.[130] It remains to be seen whether agonistic approaches will have a future place in the treatment of RA.

## CONCLUSION

**KEY POINT**

**Rituximab and abatacept both have an established role in the pharmacologic management of RA.**

Despite recent advances in understanding the optimal use of nonbiologic DMARD therapies and the considerable success of biologic therapies targeting TNF, a substantial proportion of patients with RA remain refractory to or intolerant of these therapeutic modalities. The data discussed in this chapter illustrate that there is a role in clinical practice for newer biologic agents with specificity for cellular targets. In particular, depletion of B cells with the monoclonal antibody rituximab results in sustained improvement in the signs and symptoms of RA after just two doses (one treatment cycle), with little evidence of drug-related toxicity despite the profound and lasting depletion of B cells. Similarly, inhibition of T cell co-stimulation by abatacept demonstrates clear clinical efficacy within 16 weeks and, in some cases, additional improvement for 1 year or beyond, with acceptable safety. This observation is in marked contrast to the previously observed unfavorable benefit-risk ratio associated with a T cell–depleting strategy using Campath-1H. The response of patients with RA to this wide spectrum of therapeutic strategies attests to the complexity and heterogeneity of the syndrome and provides further impetus for studies that use these therapies to enhance our understanding of disease pathogenesis.

Although both rituximab and abatacept have been shown to benefit a significant proportion of patients with RA—whether they are naïve to DMARDs or have experience with either biologic DMARDs, nonbiologic DMARDs, or both—to date very little is known about the comparative effects of these treatment approaches on symptoms and signs of disease or on inhibition of structural damage. Furthermore, despite some pointers to biomarkers that might optimize treatment outcomes with a particular therapeutic approach at the cohort level, such as seropositivity in patients with RA who are treated with rituximab, as yet no biomarkers reliably inform the best choice of therapy on an individual basis. Rituximab and abatacept are a welcome addition to the biologic armamentarium for RA, and both agents may also have a role in the pharmacologic management of rheumatic disorders beyond RA alone. It is anticipated that further clinical research and experience in the use of these biologic therapies will help better inform optimal treatment strategies.

CHAPTER 65

# Novel Intra-cellular Targeting Agents in Rheumatic Disease

Stanley Cohen

**KEY POINTS**

- During the last 25 years, key pathways responsible for signal transduction to the nucleus after ligand binding to cellular receptors on immune cells have been established.
- Protein kinases that phosphorylate intra-cellular proteins are major players in signal transduction.
- Oral small-molecule inhibitors of downstream protein kinases, including p38 MAP kinase and MEK inhibitors, have been investigated, very limited success in rheumatoid arthritis (RA) clinical trials.
- Janus kinase (JAK) inhibitors have been successfully developed as therapies for various malignancies and for RA.
- The efficacy and safety of JAK inhibitors are similar to biologic disease-modifying anti-rheumatic drugs. The observed increase in herpes zoster and, possibly, opportunistic infections, may be unique to these inhibitors.
- Spleen tyrosine kinase (SYK) inhibitors have been associated with modest benefit and significant adverse events.
- Oral small-molecule phosphodiesterase inhibitors are approved for treatment of psoriatic arthritis with modest benefit in skin and joint disease.
- Other signal transduction pathways—BTK and PI3k—are being targeted in clinical trials.

Advances in treatment for rheumatoid arthritis (RA) during the past 2 decades have resulted in dramatic improvements in quality of life for these patients. The development of biologic therapies targeting molecules involved in the pathogenesis of RA has led to significant improvements in the signs and symptoms of disease in as many as 60% to 70% of patients, and resulted in remission in 10% to 50% of patients, depending on the definition of remission and disease duration.[1,2]

Biologic therapies, however, have limitations. More than half of patients continue to have active disease and require either subcutaneous or intravenous administration. These therapies are associated with significant expense and can induce immunogenicity. During the last 25 years, the intracellular signaling pathways involved in signal transduction from the cell surface to the nucleus after ligand-receptor binding to its receptor have been identified. This improved understanding of these pathways has provided opportunities for development of small molecule-therapies that could target these pathways. Interruption of the signaling cascade has been demonstrated in pre-clinical models to reduce pro-inflammatory cytokine production, with improvement in animal models of inflammatory arthritis similar to that seen with biologics.[3,4,5] During the last decade, multiple clinical trials in patients with RA that evaluated small molecules targeting specific kinases have been conducted. The majority of these investigational trials failed because of limited efficacy or significant toxicity. In 2012, tofacitinib, a Janus kinase (JAK) inhibitor, was approved for RA treatment in the United States and Japan, and other JAK inhibitors are under development. This chapter will focus on the various molecules that have been evaluated as potential RA therapies or are presently undergoing active investigation.

## SIGNAL TRANSDUCTION PATHWAYS

Research during the last 25 years has firmly established that reversible protein phosphorylation is a fundamental mechanism of cell signaling.[6,7] Protein kinases are the enzymes that catalyze the transfer of the γ phosphate of a purine nucleotide triphosphate (i.e., adenosine triphosphate [ATP] and guanosine triphosphate [GTP]) to the hydroxyl groups of their protein substrates. A total of 518 kinases have been identified, with the majority selectively phosphorylating serine or threonine peptides. Ninety kinases that phosphorylate tyrosine (protein tyrosine kinases) have been identified that play major roles in signal transduction. These tyrosine kinases exist as receptor tyrosine kinases, such as epidermal growth factor and platelet-derived growth factor, but the majority of receptors interact directly with intra-cellular kinases to facilitate signal transduction. Protein phosphorylation ultimately links membrane events to calcium modulation, cytoskeletal rearrangement, gene transcription, and other canonical features of lymphocyte action.[8]

Many of the major classes of receptors that trigger immune cell activation are linked to protein phosphorylation and are physically associated with protein kinases (Figure 65-1). Multiple signaling pathways after ligand-receptor interaction have made targeting pathways for therapeutic benefit difficult in inflammatory arthritis because of the redundancy of these pathways. Inhibition of one signaling component may be compensated for by increased signaling through an alternative pathway, resulting in incomplete inhibition.

The initial event in T cell receptor (TCR), B cell receptor (BCR), and NK (natural killer) and Fc receptor signaling is phosphorylation of receptor subunits on tyrosine residues.[9,10] Cytokine receptors, especially type I/II cytokine receptors, signal directly by activating kinases, which phosphorylate receptor subunits and thereby initiate signaling in

T cells and NK cells. Type I and type II cytokine binding activates JAK, which then phosphorylates cytokine receptors, allowing STAT (signal transducer and activator of transcription) DNA-binding proteins to attach to receptors and become phosphorylated. STAT activation leads to their dimerization and translocation to the nucleus, where they regulate gene expression. In B cells, antigen binding leads to activation of three main protein tyrosine kinases (PTKs): the SRC-family kinases, LYN and SYK, and the TEC-family kinase, Bruton's tyrosine kinase (Btk). SYK phosphorylates adaptor protein BLNK and, along with Btk, activates phospholipase Cγ (PLCγ).[11] Activation of PLCγ leads to the release of intra-cellular $Ca^{2+}$ and activation of protein kinase C (PKC), which activate mitogen-activated protein kinases (MAP kinases). The MAP kinase cascade activates transcription factors nuclear factor-κB (NF-κB) and nuclear factor of activated T cells (NFAT), allowing gene regulation.

Upstream and downstream protein kinases in these pathways have been targeted in oncology as well as inflammatory disorders (Table 65-1). Initial concerns existed about the safety of kinase inhibitors because of the potential lack of specificity to inhibit a specific kinase.[12,13] This lack of specificity has become less of an issue in the clinic with the successful development of multiple and less selective kinase inhibitors, initially in oncology. Imatinib was the first tyrosine kinase inhibitor approved in oncology for chronic myeloid leukemia, and has been highly effective with acceptable toxicity. Subsequently, less selective tyrosine kinase inhibitors have been developed for chronic myelogenous leukemia (CML) treatment.[14,15] Even though off-target kinases are impacted by these inhibitors, safety issues have been acceptable. A total of 13 kinase inhibitors have been approved in oncology, including therapeutics for treatment of renal cell carcinoma and non–small cell lung cancer. The acceptable safety profile has stimulated efforts to develop kinase inhibitors in inflammatory diseases, such as RA, psoriasis, and inflammatory bowel disease.

## P38 MAP KINASE INHIBITORS

The MAP kinases were identified in the 1990s as involved in the production of pro-inflammatory cytokines after cell stimulation by various stressors.[16,17] There are three major families of MAP kinase: extra-cellular signal-regulated kinase (ERK), c-JUN N-terminal kinase (JNK), and p38 (Figure 65-2). The MAPs are intra-cellular enzymes that transmit a signal to the nucleus, resulting in gene transcription.[18,19] Complex parallel and crossover signaling cascades link the three main MAP kinase families. MAP kinase activation is mediated by upstream MAP kinase kinases (MKKs), which are also activated by MKK kinases (MKKK or MAP3K).

p38 MAP kinase is a key regulator of pro-inflammatory cytokine production. Varied cellular stresses, such as inflammatory cytokines, pathogens, and growth factors, activate kinases that regulate the expression of key genes, resulting

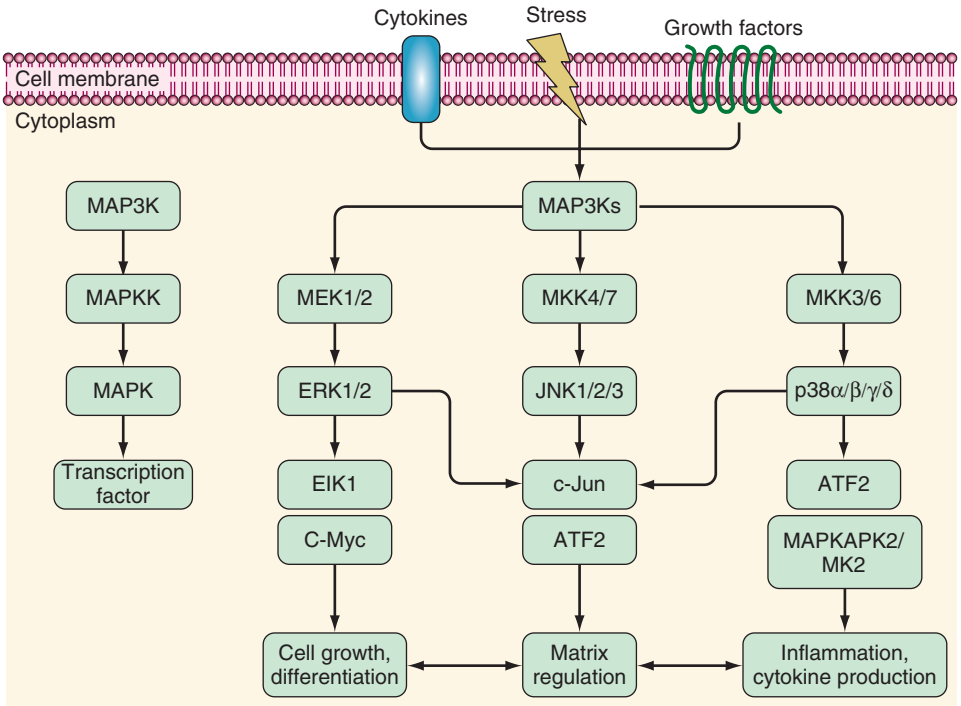

**Figure 65-2** Simplified mitogen-activated protein kinase (MAPK) pathway. ATF, Activating transcription factor; ERK, extra-cellular signal-regulated kinase; JNK, c-JUN N-terminal kinase; MKK, MAPK kinases.

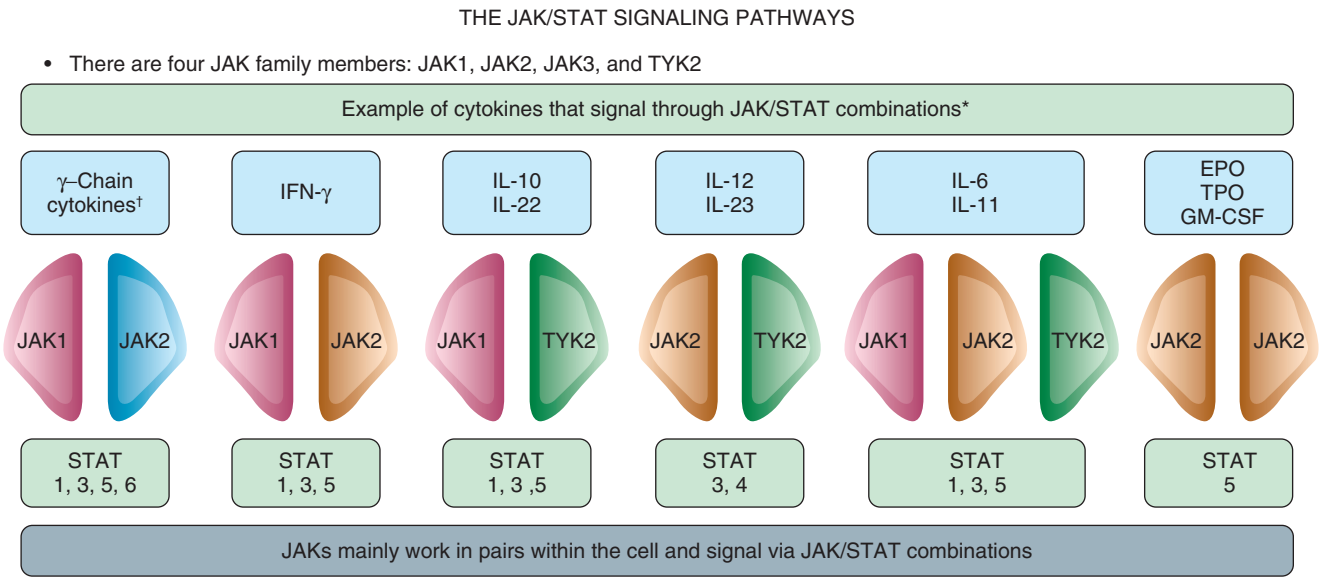
in transcriptional activation of TNF, IL-1 and IL-6, cyclooxygenase (COX-2), and matrix metalloproteinases (MPPs). p38 activation and phosphorylation is regulated by two upstream kinases, MKK3 and MKK6, which are phosphorylated by multiple MAP3Ks. There are four isoforms of p38—α, β, γ, and δ—and p38α is the isoform thought to be the most important regulator of cytokine expression. Phosphorylated activated p38 MAP kinase is also found in the synovial lining and endothelium of vessels in RA synovium.[20] The p38 MAP kinases were the first kinases targeted after the observation that inhibition of this pathway could reduce lipopolysaccharide (LPS)-induced TNF and IL-1 production by monocytes.[21] Several pre-clinical studies have demonstrated that inhibition of p38 MAP kinase suppresses production of inflammatory cytokines, and pre clinical animal models demonstrated reduction in paw swelling and joint damage.[22,23] Several clinical trials have been performed with investigational p38 inhibitors. The p38α isoform has been the primary target in clinical trials. A 24-week double-blind randomized, placebo-controlled clinical trial (RCT) of SCIO-469 monotherapy, a p38α MAP kinase inhibitor, was performed in 302 patients with active RA randomly assigned to receive oral SCIO-469, 30 or 60 mg, three times per day, or 100 mg extended-release daily, or placebo.[24] The primary efficacy endpoint was the ACR20 response rate at 12 weeks. At week 12, no difference was seen between the SCIO-469–treated patients compared with placebo for the ACR20 or ACR50 response. A decrease in acute phase reactants, C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR), was seen in the SCIO-469–treated patients at week 1, which was not sustained to week 4. This transient reduction in CRP has been reported with other p38 MAP kinase inhibitors. Adverse events (AE) occurring more frequently in SCIO-469–treated patients included rashes, dizziness, constipation and arthralgias, and liver function abnormalities, which were dose related.

Pamapimod, another selective inhibitor of the α isoform of p38 MAP kinase, was studied in a 12-week RCT in 204 patients with active RA. The study compared different once-daily doses of pamapimod to methotrexate (MTX), which was titrated to 20 mg/week by week 8.[25] The primary endpoint was the ACR20 response at week 12. At week 12, pamapimod-treated patients had ACR20 responses numerically lower than patients treated with MTX. Statistically superior results were seen with MTX for ACR50 response and decreases in disease activity score (DAS)28. A transient reduction in CRP levels at week 1, that resolved by week 2, was seen in the 300 mg pamapimod group. AEs increased in a dose-dependent manner and included maculopapular rashes, dizziness, and elevated liver function tests (LFTs). This adverse event profile was similar to that seen with all of the p38 inhibitors evaluated in clinical trials. A companion dose-ranging study that evaluated pamapimod in patients with RA who had active disease despite MTX therapy also failed to show efficacy compared with placebo.[26] Based on the results of these two studies, development efforts of this molecule in RA were terminated.

Two 12-week placebo-controlled RCTs were conducted in Eastern Europe to evaluate VX-702, a highly selective inhibitor of the p38α isoform of MAP kinase.[27] This molecule has little or no central nervous system (CNS) penetration, as was seen with predecessor molecules, and researchers thought it might be associated with less dizziness and headaches. Patients' ACR responses to the dose range investigated were not significantly different from placebo. No new safety issues were reported. Because of VX-702's limited efficacy, development of this therapy was terminated.

Two subsequent reviews of MAP kinase inhibitors proposed theories of why inhibition of p38 MAP kinases in animal models was successful, whereas studies in patients with RA were not.[28,29] Issues raised include dose limitations caused by toxicity, altered biodistribution of newer molecules that prevent CNS penetration, incorrect isoform targeting, and the fact that p38α may have a regulatory role in the induction of anti-inflammatory cytokines.[30] The most plausible explanation, which is supported by the transient acute phase response, is the redundancy of signaling networks, such that blocking a downstream molecule such as p38 would not block upstream kinases that can redirect the signaling flow. Recognition of this concern has stimulated efforts to target more upstream protein kinases, and no further trials in RA with p38 inhibitors are ongoing.



## MEK INHIBITORS

MEK is a MAPKK involved in growth factor signal transduction and cytokine production. Inhibitors of MEK demonstrated efficacy in pre-clinical models of RA.[31] Based on the pre-clinical observations, ARRY-438162, an oral inhibitor of MEK1/MEK2, was evaluated in a double-blind randomized clinical trial. The results were presented in the 2010 European League against Rheumatism (EULAR) meeting, although never published. In this study, 201 patients with RA with active disease despite MTX treatment were randomly assigned to receive various doses or placebo. The primary endpoint was ACR20 response. No difference between the active treatment groups and placebo was demonstrated ($P = 0.459$). The most common active adverse events were skin rashes and diarrhea that were dose related. Serious AEs were rare. No additional trials of molecules targeting MEK in RA are ongoing at the present time.

## SPLEEN TYROSINE KINASE INHIBITORS

SYK inhbitors have been evaluated as a potential treatment for RA. SYK is a nonreceptor protein tyrosine kinase that is a modulator of immune signaling in cells bearing Fcγ-activating receptors, including B cells, mast cells, macrophages, neutrophils, eosinophils, basophils, and synoviocytes.[32,33] SYK binds to the cytoplasmic region of these receptors that contain the immune-receptor tyrosine-based activation motif (ITAM). Receptor binding results in ITAM phosphorylation activating SYK (Figure 65-3). This motif is located in the cytoplasmic portion of FcγR, FcεR, Igα (B cells), CD3ξ (T cells) and integrins.[34] SYK activation activates downstream MAP kinases, PI3K, and PLCγ, with a resultant increase in IL-6 and MMP production.

These observations have led to interest in SYK as a potential target for treatment of RA.[35] SYK has been found to be activated in synoviocytes, and activation of SYK is important for cytokine and metalloproteinase production induced by TNF in fibroblast-like synoviocytes from patients with RA.[36] Pre-clinical models suggest inhibition of SYK could ameliorate inflammatory arthritis.[37-39] An oral agent that inhibits SYK, fostamatinib disodium, a prodrug of the active metabolite R406, was evaluated in pre-clinical models of inflammatory arthritis and found to be effective. Based on this observation, fostamatinib was evaluated in patients with RA in four phase II clinical trials[40-43] and one phase III[44] clinical trial. Doses studied were 100 mg, once per day, 100 mg twice per day, or 150 mg twice per day. Statistically superior improvements in clinical outcomes at 12 to 24 weeks were seen, as measured by ACR response and change in DAS28 score in two of the phase II randomized clinical trials evaluating fostamatinib in combination with MTX in nonbiologic disease-modifying anti-rheumatic drug (DMARD) nonresponders. Clinical response was seen

**Figure 65-3** Janus kinase (JAK)/signal transducer and activator of transcription (STAT) signaling pathways. EPO, Erythropoietin; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; TPO, thrombopoietin; TYK, tyrosine kinase.

as early as week 1. In a third phase IIb, 24-week trial, fostamatinib was evaluated as monotherapy compared with placebo and an active comparator toadalimumab.[43] The primary endpoint was the change in DAS28 (CRP) at week 6. Improvement in the fostamatinib-treated patients was seen compared with placebo, but less than that seen with adalimumab.

A 3-month RCT of fostamatinib, 100 mg twice per day or placebo, was conducted in 219 patients in whom biologic agents had previously failed, with the primary endpoint the ACR20 response at month 3.[43] MRI images of patients' wrists and hands were evaluated in a subset of patients. The study failed to meet its primary endpoint at month 3; there was no statistical difference in the ACR20 response between the two groups. Although the study failed, there was a difference in change from baseline between the fostamatinib and placebo groups in MRI synovitis scores.

Because of the efficacy observed in the nonbiologic DMARD-incomplete responder phase II trials, a 52-week phase III multinational RCT was conducted in 918 patients with RA with active disease despite MTX.[44] Patients were randomly assigned to either fostamatinib, 100 mg twice daily; 100 mg twice daily for 4 weeks, then 150 mg daily; or placebo for 24 weeks, then open-label fostamatinib, 100 mg twice daily. The co-primary endpoints were change from baseline in ACR20 response and change in modified Total Sharp van der Heijde score (mTSS) at week 24. Both fostamatinib cohorts achieved a statistically superior ACR20 response compared with placebo-treated patients (44.4% to 49% vs. 34.2%; $P = 0.001$, $P = 0.006$), respectively, but this was a lower response than seen in the phase II program. Additionally, there was no statistical difference in the co-primary endpoint change in mTSS between fostamatinib and placebo.

In all of the phase II/III trials, a dose-dependent increase in AEs, including diarrhea, neutropenia, dizziness, hypertension, and elevated LFTs were observed. Adverse events were more common in the fostamatinib cohorts, including hypertension, diarrhea, neutropenia, and LFT elevations. Serious adverse events occurred in 2.9% to 4.9% fostamatinib-treated patients and 1.6% placebo-treated patients. A small number of malignancies were seen in the fostamatinib cohorts and none in the placebo treated patients. A meta-analysis of the safety profile of fostamatinib in the development program reported the relative risk of the following AEs with fostamatinib: hypertension, 2.80 (confidence interval [CI], 1.02 to 8.43); diarrhea 5.20 (CI, 3.19 to 8.49); neutropenia, 9.24 (CI, 2.22 to 38.42); and LFTs, 2.93 (CI, 1.02-8.43).[45] Based on the failure of fostamatinib to achieve the primary endpoint in the phase III clinical trial and the AE profile, development of the molecule for RA development was terminated.

A second SYK inhibitor has been evaluated in RA patients. MK-8457 is a novel inhibitor of SYK and zeta-chain–associated protein kinase 70 (ZAP70), and was considered to be a more specific SYK inhibitor with less off-target effects. Two small phase II dose-ranging trials utilizing an adaptive design were conducted.[46,47,48]MK8457 was found to be effective in the MTX incomplete responders, similar to fostamatinib, but not in the patients who had not responded to previous TNF inhibitors. Toxicity was significant in both studies, primarily serious infectious episodes, including opportunistic infections. Diarrhea, nausea, and elevations in LFTs were also reported. Hypertension was not seen, possibly because of the limited off-target impact on vascular endothelial growth factor. Because of the significant toxicity noted and failure to see the benefit in TNF in incomplete responders, development of this molecule was terminated.

Both molecules targeting SYK failed as therapies for RA. Significant toxicity was seen with both molecules, including serious infectious episodes, limiting enthusiasm for this kinase as a target in patients with inflammatory arthritis.

## JANUS KINASE INHIBITORS

JAKs are protein tyrosine kinases that bind the cytoplasmic region of transmembrane cytokine receptors and mediate signaling through type 1 and type 2 cytokine receptors.[49] After receptor-ligand interaction, various JAKs are activated, resulting in tyrosine phosphorylation of the receptor and subsequent activation of STATs (signal transducer and activators of transcription), which act as transcription factors. JAK/STAT signaling mediates cellular responses to multiple cytokines and growth factors. These responses include proliferation, differentiation, migration, apoptosis, and cell survival, depending on the signal and cellular context. Activated STATs enter the nucleus and bind to specific enhancer sequences in target genes, impacting their transcription.[50]

JAKs consist of four types: JAK1, JAK2, JAK3, and TYK. The JAKs signal as pairs (see Figure 65-3). JAK3 is primarily expressed in hematopoietic cells and is critical for signal transduction from the common γ-chain of the receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 on the plasma membrane to the nuclei of immune cells. JAK3 only signals in combination with JAK1. These cytokines are integral to lymphocyte activation, function, and proliferation. JAK3-knockout mice have defects in T and B lymphocytes and NK cells, with no other defects reported. Humans lacking JAK3 develop a severe combined immunodeficiency (SCID), with a deficiency in NK cells and T lymphocytes.[51]

JAK1 and JAK2 were initially not considered as potential therapeutic targets because knocking out these kinases results in germline lethality.[10] However, JAK1/JAK2 inhibitors are under development to treat RA. Ruxolitinib, which has selectivity for JAK1/2, has been approved for myelofibrosis.[52,53] Hormone-like cytokines erythropoietin, thrombopoietin, growth hormone, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, and IL-5 all signal through JAK2. IL-6, IL-10, IL-11, IL-19, IL-20, IL-22, and IFN-α, IFN-β, and IFN-γ signal through JAK1. Baricitinib, under development for RA, preferentially inhibits JAK1/JAK 2.

TYK2 facilitates signaling for IL-12, IL-23, and type 1 IFNs.[54] TYK2 pairs with either JAK1 or JAK2 to facilitate signaling. At present no specific TYK2 inhibitors are under development for RA.

Additional JAK inhibitors under development have been demonstrated to be potentially more specific JAK1 (GLPG0634) or JAK3 inhibitors (VX-509) with less off-target inhibition. The assays evaluating specificity of the JAK inhibitors vary depending on the substrate utilized,

whether it be biochemical, enzymatic, or cellular, which makes the comparative data difficult to interpret. For example, tofacitinib at the doses used in the clinic demonstrates substantial nanomolar inhibitory potency in enzymatic assays against all JAK family kinases except TYK2, but in cellular assays it shows functional specificity for JAK1 and JAK1/3 versus JAK2.[55] Most now consider tofacitinib to be a pan-JAK inhibitor. A recent preliminary publication demonstrated that clinical profiles of cytokine inhibition for a number of JAK inhibitors in RA are strikingly similar when efficacious doses are considered, suggesting possible limited potential for differentiation of these therapeutics based on their JAK pharmacology.[56]

## Tofacitinib

Tofacitinib is a JAK inhibitor that has been approved by the U.S. Food and Drug Administration (FDA) for patients with RA with active disease, despite MTX treatment at a dose of 5 mg, twice daily, in combination with nonbiologic DMARDs or as monotherapy (Figure 65-4). Tofacitinib has not been approved by the European Medicines Agency (EMA) because of concerns regarding safety. Tofacitinib is also being evaluated for treatment of psoriasis, psoriatic arthritis (PsA), and inflammatory bowel disease. It was under development for treatment of patients undergoing renal transplantation, but this program was discontinued because of toxicities, including serious infections and post-transplantation lymphoproliferative disease.[57] The dose of tofacitinib used in the transplantation program was higher than the dose approved for RA and was used in combination with other potent immunosuppressants.

Tofacitinib has been demonstrated in cellular in vitro assays to reversibly inhibit JAK1, JAK2, JAK3, and, to a lesser extent, TYK2, with functional selectivity for JAK1/3 and JAK1/2 signaling versus JAK2/2. As previously noted, the clinical relevance of this selectivity is unclear.[58] Inhibition of JAK1/3 by tofacitinib will inhibit signaling for cytokines that bind receptors that utilize the common γ-chain receptor, such as IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21.[59] Reduction in NK cells has been demonstrated with tofacitinib treatment.[53] It has been postulated that IL-6 inhibition, which signals through JAK1, may play a role in the efficacy of the molecule as well as AEs such as neutropenia and hyperlipidemia, which have been seen with tocilizumab, a monoclonal antibody to the IL-6 receptor. Recent observations suggest that IL-17 production by T helper 17 cells is also inhibited.[60] Tofacitinib does not block IL-1 or TNF signaling.

The pharmacokinetic profile of tofacitinib is characterized by rapid absorption (peak plasma concentrations are reached within 0.5 to 1 hour), rapid elimination (half-life of approximately 3 hours), and dose-proportional increases in systemic exposure.[61] Steady-state concentrations are achieved in 24 to 48 hours with minimal accumulation after twice-daily administration. Tofacitinib is eliminated through both hepatic (70%) and renal clearance (30%). The metabolism is primarily through CYP3A4 and less so by CYP2C19. At the approved dosage, no extrinsic factors or drugs require dose modification based on pharmacokinetic evaluation in pre-clinical studies. The pharmacodynamic effects of tofacitinib have been demonstrated to persist for 4 to 6 weeks after dosing.[62] Tofacitinib is a teratogen, and premenopausal women should utilize contraception and avoid conception for 4 to 6 weeks after the last dose.

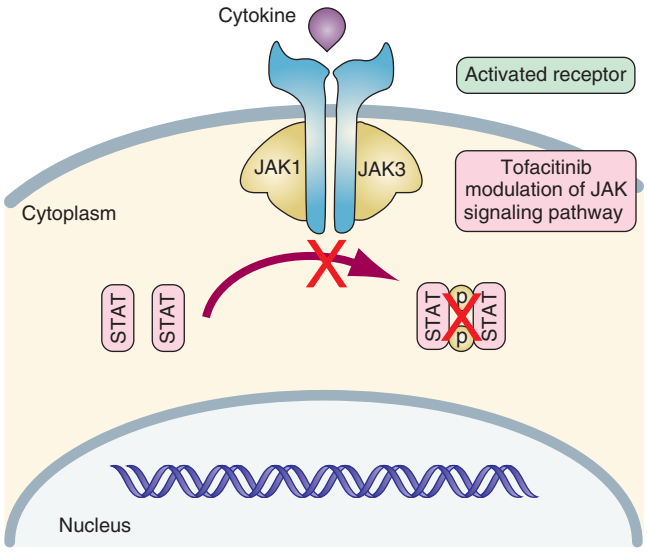

**Figure 65-4** Tofacitinib Janus kinase (JAK) inhibition. STAT, Signal transducer and activator of transcription.

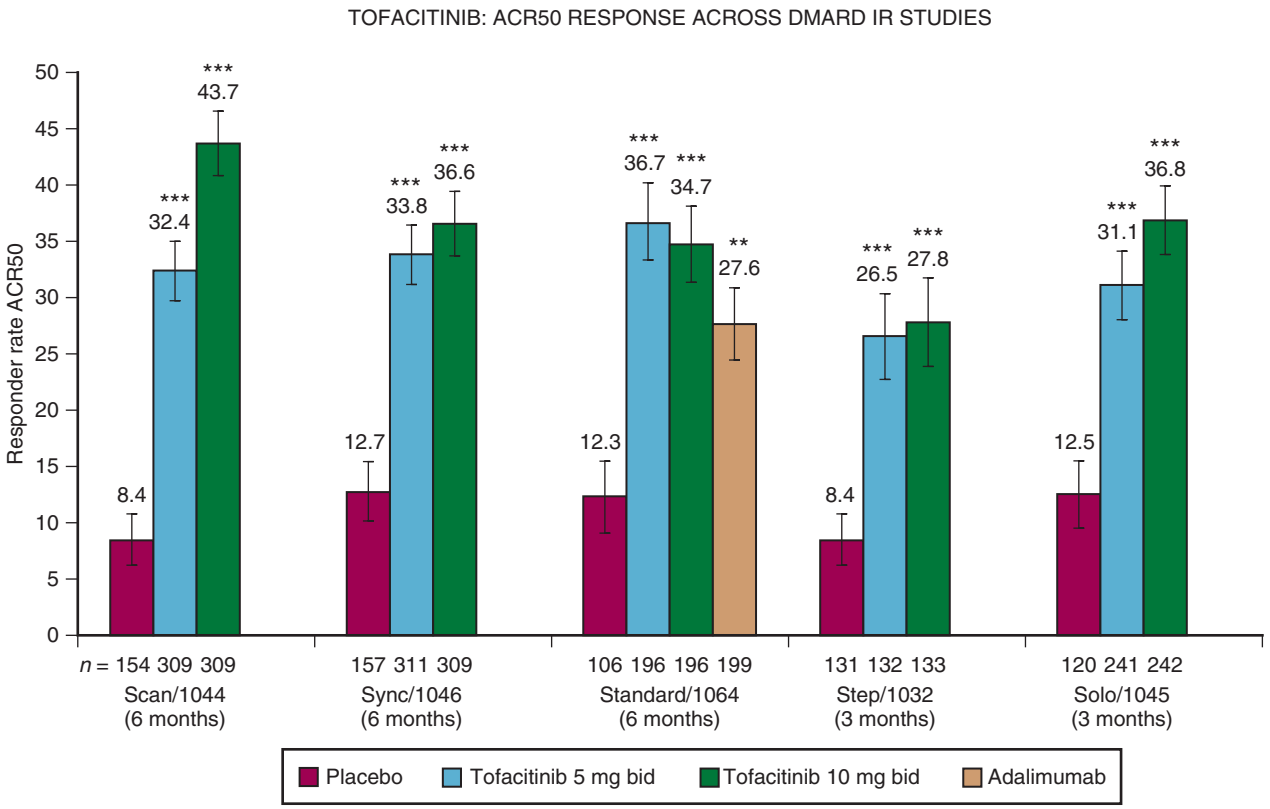
### Efficacy

Tofacitinib was extensively studied before approval. Eight placebo-controlled, randomized, phase II studies were performed in which tofacitinib was given as monotherapy or in combination with background MTX. The phase II program included 1600 patients, and evaluated tofacitinib doses from 1 mg to 30 mg twice daily, for treatment durations ranging between 6 weeks and 6 months. Consistent improvement in clinical outcomes were seen with doses of 5 mg twice daily or greater, but toxicity was greater at higher doses.[63-65] Based on the efficacy and safety profile from the phase II clinical trials, tofacitinib, 5 mg twice daily and 10 mg twice daily doses were progressed to phase III trials.



Six phase III RCTs evaluating tofacitinib in RA were conducted in the development program.[66-71] Two of the studies were conducted in patients with RA with active disease despite MTX treatment ("scan, standard"), and one study evaluated patients on MTX or other nonbiologic DMARDs ("sync"). Adalimumab was compared with tofacitinib in the "standard" trial. TNF incomplete responders on background MTX were evaluated in the 6-month "step" study, and tofacitinib monotherapy was evaluated in the 6-month "solo" study (Figure 65-5). The "start" study compared MTX with tofacitinib 5 mg and 10 mg twice daily in MTX-naïve patients with RA during 24 months. Radiographic outcomes were evaluated in the "scan" and "start" studies. A long-term extension (LTE) protocol is ongoing, with more than 12,664 patient-years exposure.[72] At the time of approval of the 5 mg twice daily dose by the FDA, 4800 patients had participated in the clinical trial program.

The clinical trials were conducted globally, with 46% of the patients enrolled outside of North America. In the DMARD incomplete responder population, patients enrolled were 18 to 86 years of age (mean age, 50 to 56

years, 15% ≥65 years), and the majority were women (80% to 87%) with long- standing disease (mean age, 5.7 to 13 years), and high disease activity (DAS-28-4 [ESR] of 5.83 to 6.71). Tofacitinib consistently and significantly improved signs and symptoms of RA, physical functioning, and patient-reported outcomes, such as fatigue, pain, and health-related quality of life (Figures 65-6 and 65-7). Improvements in structural benefit as measured by the mTSS was observed at the 10 mg twice-daily dosage in the MTX nonresponsive responder population, but did not achieve statistical significance at the 5 mg twice-daily dosage. Improvement was demonstrated as early as 2 weeks of treatment. Efficacy with monotherapy was similar to the results with combination therapy with nonbiologic DMARDs. ACR20 responses were in the 50% to 60% range across the studies, with ACR50 rates of 30% to 40% and ACR70 rates of 15% to 20%. ACR responses were comparable to adalimumab in the "standard" study. In the "step" study evaluating TNF inhibitor nonresponders, ACR20 responses were slightly lower, at 41% to 48%, with ACR50 responses of

27% and ACR70 responses of 10% to 13%. In all of the trials, tofacitinib was statistically superior to placebo for ACR response at study endpoint, as well as improvement in the Health Assessment Questionnaire (HAQ)-DI. Although both doses were efficacious, a dose response in efficacy was suggested because the 10 mg dose was superior to the 5 mg dose for the higher threshhold clinical endpoints, such as ACR70, DAS-28 remission, low disease activity state (LDAS), and HAQ-DI improvement.[73]

The final phase III study was the oral "start" trial that compared monotherapy tofacitinib, 5 mg twice daily and 10 mg twice daily with MTX (mean dose, 18.5 mg) in 985 patients with RA who had not previously received therapeutic doses of MTX.[71] The co-primary endpoints at month 6 were the mean change from baseline in the mTSS score and the proportion of patients with an ACR70 response. The patients enrolled had a mean disease duration of 2.7 to 3.4 years and mean baseline DAS-28 ESR of 6.5 to 6.6. Of the patients, 81% to 86% were seropositive for rheumatoid factor (RF) or cyclic citrullinated protein antibodies. Mean changes in the mTSS from baseline to month 6 were significantly smaller in the tofacitinib groups than in the MTX group (0.2 in the 5 mg tofacitinib group and <0.1 point in the 10 mg tofacitinib group, compared with 0.8 in the MTX group [$P < 0.001$ for both comparisons]). Based on this trial, the FDA allowed the claim for slowing of radiographic progression. Among the patients receiving tofacitinib, 25.5% in the 5 mg group and 37.7% in the 10 mg group had an ACR70 response at month 6, compared with 12.0% of patients in the MTX group ($P < 0.001$ for both comparisons (see Figure 65-7). The 24-month results from this trial have demonstrated persistent improvement in patient-reported outcomes in patients remaining on the study for both doses of tofacitinib and MTX.[74]

## Safety

In the phase II and III studies, the most common adverse events were upper respiratory infections, headache, nasopharyngitis, and diarrhea, which were seen slightly more often in the tofacitinib patients than in the placebo group. The rate of serious adverse events (SAE) with tofacitinib at both doses was similar to placebo and adalimumab (9.76 to 11.8/100 patient-years, tofacitinib; 15.02/100 patient-years, placebo). The most common SAE was pneumonia. Similar rates of SAES were seen in the long-term extension protocol, with pneumonia again the most common reported SAEs. Incidence rate for serious infectious episodes was 2.9/100 patient-years in the phase III trials similar to that seen with biologic therapies. In the long-term extension trials, the rate was 2.3/100 patient-years for the 5 mg dose and 4.06/100 patient-years for the 10 mg dose, which was statistically different because the confidence intervals did not overlap.[75] The rates of adverse events reported in the

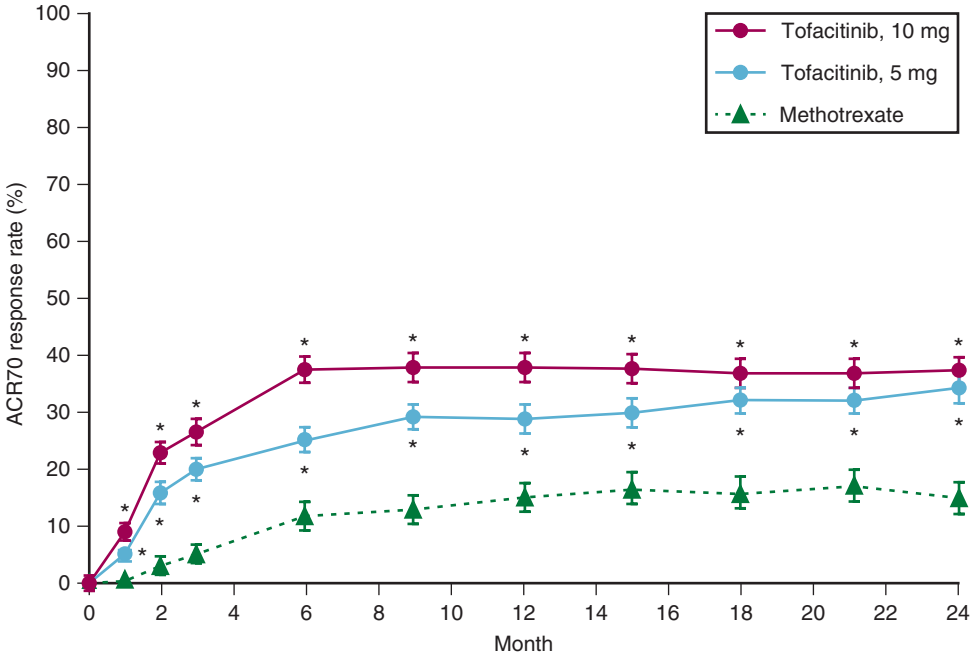

**Figure 65-8** "Start" Study: American College of Rheumatology 70 (ACR70) clinical results over time.

development program were similar to that seen with biologic DMARDs except for an increased incidence of herpes zoster (Figure 65-8).

Nonserious or serious herpes zoster infections were reported in 346 patients in the phase II and phase III clinical trials and the LTE population (incidence rate, 4.27 events/100 patient-years). Incidence rates of herpes zoster infection were 2.81 events/100 patient-years with adalimumab and 1.49 events/100 patient-years with placebo in the phase III population. Rates of herpes zoster infection were similar in patients treated with tofacitinib, 5 mg twice daily and 10 mg twice daily (phase III: 4.39/100 patient-years and 4.23/100 patient-years, respectively; LTE: 4.18 and 4.50/100 patient-years, respectively). A higher rate of herpes zoster was reported in Asian patients (6.75/100 patient-years). This increased rate of herpes zoster has not been previously reported with nonbiologic DMARDs or biologic DMARDs. The overall incidence rates for herpes zoster infections in patients with tofacitinib were stable with time, and the majority of these cases were not considered serious. Because of this observation, if possible, patients with RA should be vaccinated for herpes zoster before initiating tofacitinib.

In phase II and III and the LTE population, tuberculosis (TB) was reported in 16 patients: 4 from the Philippines, 3 from Korea, 2 each from India and China, and 1 each from Japan, Thailand, Mexico, the United States, and Spain. Cases of both pulmonary and extrapulmonary TB were reported. The incidence of TB in the randomized clinical trials was consistent with those reported for TNF inhibitors (0.02 [global] to 2.56 [South Korea]) and nonbiologic DMARDs (0.01 [global] to 0.28 [South Korea]). Screening for latent TB is indicated before initiating tofacitinib.

Excluding cases of TB, 25 patients in the clinical trials and LTE population experienced an opportunistic infection (0.30 events/100 patient-years [95% CI, 0.20 to 0.44]). Two cases of multidermatomal herpes zoster, 8 patients with esophageal candidiasis (several were incidental findings on endoscopies performed for other reasons), 6 patients with cytomegalovirus infection/viremia, 3 patients with cryptococcal infection (2 pneumonia, 1 meningitis), 3 patients with *Pneumocystis* pneumonia, 2 patients with nontuberculous mycobacteria in the lung, and 1 patient with BK virus encephalitis.

The overall mortality rate of tofacitinib, malignancy risk, and lymphoma incidence in the phase II, III, and LTE studies was consistent with the published rates in RA clinical trials for TNF inhibitors and other biologic DMARDs (Figure 65-9). Lymphomas were predominantly non-Hodgkin's B cell lymphomas.

Thirteen gastrointestinal perforations occurred in the development program on tofacitinib, and none in the placebo. These events occurred in patients on background corticosteroids and NSAIDs. The incidence rate reported at the time of approval was 0.10/100 patient-years, similar to what had been reported with TNF and IL-6 inhibitors. Use of this therapy in patients with diverticulitis should probably be avoided, similar to the present standard of care with tocilizumab, which is an IL-6 receptor inhibitor.

Tofacitinib therapy is also associated with changes in laboratory values. Dose-dependent decreases in neutrophils, as seen with TNF and IL-1/IL-6 inhibitors, were infrequently associated with AEs such as neutropenia and not associated with infection risk. Rare significant decreases in hemoglobin, which could be expected with JAK2 inhibition, were seen in the clinical trials. Lymphopenia (<500/uL) was seen in less than 1% of patients in the phase III and LTE trials, but was associated with a dramatic increased risk of serious infections (40%), and monitoring complete blood cell (CBC) and total lymphocyte counts on a regular basis (monthly for 3 months, then every 3 months), is recommended by the regulatory agencies. Discontinuation of

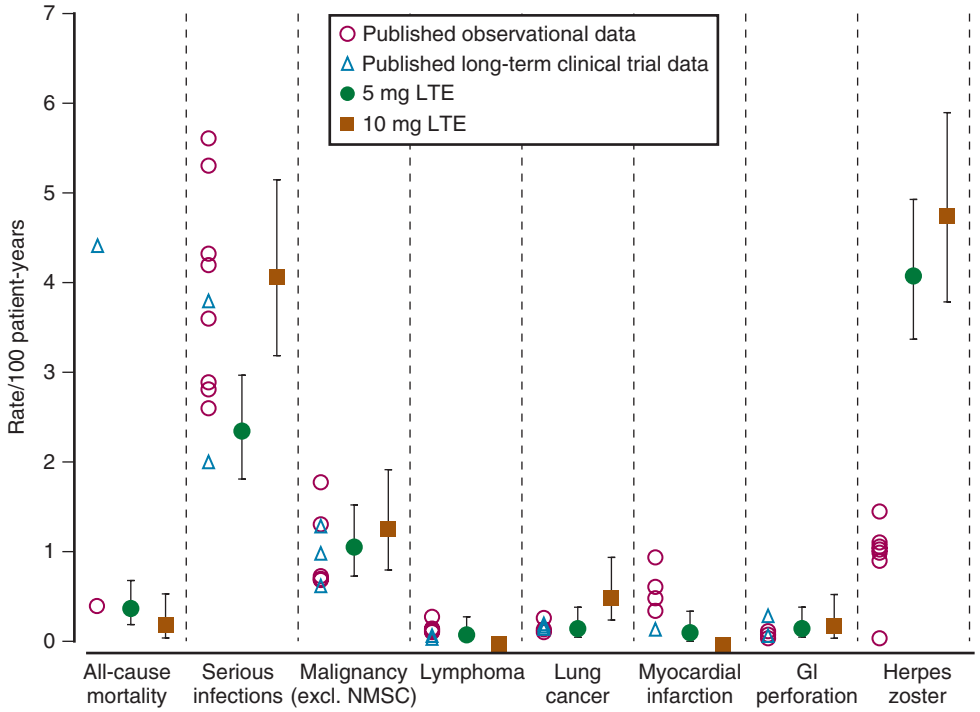

**Figure 65-9** Safety profile of tofacitinib, 5 mg and 10 mg twice daily in the long-term extension (LTE) protocols versus long-term clinical trial and observational data for biologic disease-modifying anti-rheumatic drugs. GI, Gastrointestinal.

treatment is recommended for patients with persistent lymphocyte counts (<500/μL).

Small, clinically insignificant increases in serum creatinine and increased creatinine kinase were noted and have not been associated with significant safety risks for tofacitinib. Increases in tofacitinib-treated patients were 0.02 and 0.04 mg/dL greater than placebo in the development program. The etiology of this minor change is unclear.

Mean 15% to 20% increases in low-density lipoprotein (LDL) and high-density lipoprotein (HDL) that plateaued by 3 months has been observed, similar to that seen with IL-6 inhibitors, and monitoring of lipid levels is indicated after treatment initiation. Increases in rates of cardiovascular AEs have not been shown. Atorvastatin treatment was demonstrated to be effective in patients with elevations in cholesterol on tofacitinib.[76] Monitoring of serum lipids is recommended 8 to 12 weeks after initiating therapy.

Elevations in hepatic transaminases were reported but rarely more than three times the upper limit of normal. Liver function abnormalities were more common in patients on background MTX. Laboratory changes typically normalized upon discontinuation of tofacitinib treatment. Monitoring of LFTs is recommended monthly for 3 months, then once every 3 months.

## Other JAK Inhibitors

Several other JAK inhibitors are under development (Table 65-2). Baricitinib has a selectivity for JAK2/JAK1 and less potency for JAK3, or TYK2.[77] In addition to RA baricitinib is under development to treat psoriasis and diabetic neuropathy. Baricitinib is rapidly absorbed and has a $T_{½}$ of 6 to 8 hours and is dosed once daily.[78]

**TABLE 65-2** Janus Kinase (JAK) Inhibitors in Development

| | |
|---|---|
| Baricitinib | JAK1/2 inhibitor |
| Decernotinib (VX-509) | JAK1/3 inhibitor |
| Fibotinib (GLPG0634) | JAK1 inhibitor |
| Peficitinib (ASP015K) | JAK1/3 inhibitor |
| ABT-494 | JAK1 inhibitor |

A 12-week dose-ranging phase II study in 301 patients with RA was conducted, evaluating 1 mg, 2 mg, 4 mg, and 8 mg of baricitinib as a single daily dose in combination with MTX.[79] The primary endpoint was achieved with a statistically significant difference in the ACR20 response between the combined 4 mg and 8 mg baricitinib groups (76%) compared with placebo (41%) after 12 weeks of treatment ($P < 0.001$). Data at 24 weeks and a subsequent LTE protocol through 52 weeks demonstrated persistence of efficacy at 4 mg and 8 mg of baricitinib.[80,81] Safety signals were similar between the 4 mg and 8 mg doses and were most commonly infections. Rare cases of significant anemia were seen, as would be expected with a JAK2 inhibitor. No significant difference in efficacy between the 4 mg and 8 mg doses were seen in the phase II trials. The 2 mg and 4 mg baricitinib doses were selected for the phase III trials.[82,82a]

### Fibotinib (GLPG0634)

Fibotinib (GLPG0634) is an orally available, selective inhibitor of JAK1 under development for the treatment of RA and Crohn's disease. The molecule displays a JAK1/JAK2 inhibitor profile in biochemical assays, but subsequent

studies in cellular and whole-blood assays revealed a selectivity of approximately 30-fold for JAK1 versus JAK2-dependent signaling.[83] An active metabolite of GLPG0634 has been identified, with a longer half-life than the parent molecule, supporting once-daily dosing.[84] A small, 4-week single-center study, evaluating 36 patients with RA with active disease despite MTX treatment with 100 mg twice daily and 200 mg daily, and placebo, demonstrated that 83% of patients receiving GLPG0634 achieved an ACR20 response, and half of the GLPG0634-treated patients achieved either disease remission or low disease activity. Of the placebo patients, 33% achieved an ACR20 response.[85] A second phase II 4-week, double-blind study of GLPG0634 at 30, 75, 150, and 300 mg once-daily doses, and placebo evaluated 91 biologic-naïve patients with RA who had insufficient response to MTX. GLPG0634 demonstrated efficacy at doses greater than 75 mg daily, with no additional benefit to the 300 mg dose compared with the previous results at 200 mg in the proof-of-concept study.[86] No significant safety issues were reported in these short-duration studies.

Subsequent trials are ongoing evaluating the efficacy and safety of GLPG0634 at 50 mg, 100 mg, and 200 mg dosages as combination therapy or monotherapy with 24 weeks of treatment in 875 patients with moderate to severe RA with active disease despite MTX treatment.[87,87a]

### Decernotinib (VX-509)

Decernotinib (VX-509) is a JAK inhibitor previously in development with selectivity for JAK3 over JAK1/2 and TYK2.[88] In 2011, a phase IIa clinical trial of four doses of VX-509 was reported, and data from the treatment arms of the two highest doses (100 mg and 150 mg) demonstrated statistically significant ACR20, ACR50, ACR70, and DAS-28 responses compared with placebo.[89] The 150 mg treatment arm demonstrated ACR20, ACR50, ACR70, and DAS28 responses of 66%, 49%t, 22% and –3.06%, respectively, whereas the placebo arm showed responses of 29%, 7%, 2%, and –1.25, respectively. A subsequent phase IIb, double-blind, randomized, placebo-controlled 24-week phase IIb study of VX-509 enrolled 358 people with RA with active disease despite methotrexate treatment.[91] Patients were randomly assigned to receive placebo or one of four doses of VX-509. In all VX-509 treatment groups, the proportion of patients achieving ACR20 and ACR50 and the decrease from baseline in DAS-28 were significantly greater than in the placebo group. The three highest dose groups showed ACR20 responses of between 58% and 68%, compared with 18% for placebo, and statistically significant ACR70 responses versus placebo. AEs including infections, SAEs, and hyperlipidemia, were seen more commonly with VX-509. Elevations in transaminase levels and decreases in median neutrophil and lymphocyte counts were observed in the VX-509 groups and were generally mild. Subsequent 24-week results demonstrated similar efficacy and safety results.[92] This molecule is no longer under development for RA.

### Peficitinib (ASP015K)

Peficitinib (ASP015K) is an once-daily oral JAK inhibitor that is in development for RA. ASP015K has shown selectivity of JAK1/JAK3 versus JAK2 in cell-based assays. In a 12-week, double-blind study, patients with active RA not on concomitant DMARD therapy were randomly assigned equally to once-daily ASP015K 25 mg, 50 mg, 100 mg, 150 mg, or placebo.[93] Twenty-five percent of patients had previously received TNF inhibitors. There was a dose response for efficacy with the 100 mg and 150 mg daily doses at week 12, achieving statistically significant ACR20, ACR50, and ACR70 responses compared with placebo. No difference in AEs or SAEs were reported for ASP015K compared with placebo, except for nasopharyngitis, diarrhea, and creatine phosphokinase elevation, which was reported more frequently with ASP015K. Additional trials with this molecule are ongoing.

A subsequent 12-week phase IIb dose-ranging study in MTX incomplete responders failed to achieve a statistically significant difference in the primary endpoint the ACR20 responses from placebo.[94]A statistically significant difference was seen for the change in DAS-28–CRP and DAS-28–ESR. Most common AEs were headache and hyperlipidemia.

### ABT-494

ABT-494 is a second-generation JAK1 inhibitor, which in cellular and in vivo assays, showing 74-fold selectivity over JAK2/3.[95] Clinical trials are ongoing in RA, with preliminary reports indicating response rates similar to other JAK inhibitors.

## BTK INHIBITORS

Oral Btk inhibitors (ibrutinib) have been approved for treatment of patients with mantle cell lymphoma and chronic lymphocytic leukemia who have received at least one previous therapy.[96] Btk inhibitors are in early development as a potential treatment for RA. Btk plays a prominent role in BCR signal transduction and also has a role in Toll-like receptor and FcR signaling in myeloid cells.[97] BTK is a member of the TEC family of cytoplasmic protein tyrosine kinases. In humans, mutations in BTK can result in the development of Bruton's agammaglobulinemia (known also as X-linked agammaglobulinemia), an immunodeficiency characterized by a defect in B cell development and resulting in a significant absence of circulating B cells.[98]

Upon ligand binding to the BCR, Btk is activated by upstream SRC-family kinases LYN, FYN, and SYK (Figure 65-10). Activated Btk drives phosphorylation of PLCγ and subsequent protein kinase C (PKC) activation, which in turn results in calcium flux and the activation of transcription factors, including NF-κB and NFAT, regulating the expression of downstream genes controlling proliferation, survival, and chemokines and cytokines. B cells play multiple roles in the pathogenesis of RA, including antigen presentation, inflammatory cytokine production and RF, and CCP antibody production. Rituximab, which depletes B cells, has demonstrated efficacy as treatment for patients with RA, supporting efforts to develop a small molecule Btk inhibitor that impacts B cell activation.[99]

Animal models of arthritis suggest that Btk inhibition can result in inhibition of B cell receptor–dependent cell proliferation and a reduction of inflammatory cytokine

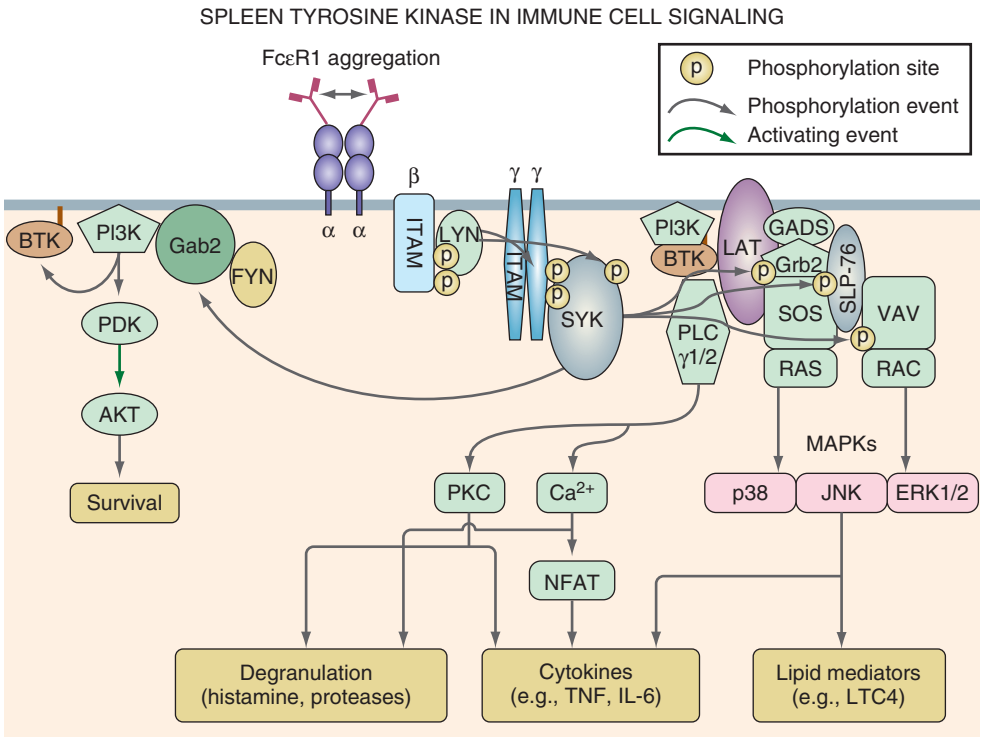

**Figure 65-10** Spleen tyrosine kinase (SYK) in immune cell signal transduction. JNK, c-JUN N-terminal kinase; LTC4, leukotrience C4; MAPK, mitogen-activated protein kinase; NFAT, nuclear factor of activated T cells; PDK, phosphoinositide dependent kinase; PKC, protein kinase C.

production from myeloid cells (including TNF, IL-1, and IL-6) by preventing signaling through the FCyRIII receptor.[100,101] Additionally, activated BTK has been demonstrated to be increased in peripheral blood B cells of patients with RA compared with controls.[102]

Early-phase trials with BTK inhibitors in RA are ongoing.[102a,103]

## PI3K INHIBITORS

PI3Ks are lipid kinases that play central role in regulation of cell cycle, apoptosis, DNA repair, senescence, angiogenesis, cellular metabolism, and motility.[104,105] They are intermediate signaling molecules and are most well known for their roles in the PI3K/AKT/mammalian target of rapamycin (mTOR) signaling pathway. PI3Ks transmit signals from the cell surface to the cytoplasm by generating second messengers—phosphorylated phosphatidylinositols—which in turn activate multiple effector kinase pathways, including Btk, AKT, PKC, NF-κB, and JNK/SAPK pathways, and ultimately result in survival and growth of normal cells.

PI3K signaling is mediated by p110 α, β, γ, and δ isoforms. Two isoforms of the catalytic subunits, p110γ and p110δ, are enriched in leukocytes, in which they promote activation, cellular growth, proliferation, differentiation, and survival through the generation of the second messengers phosphatidylinositol biphosphate (PIP2) and phosphatidylinositol triphosphate (PIP3). The functions of PI3K-δ and PI3K-γ in the differentiation, maintenance, and activation of immune cells support an important role for these enzymes in oncology, inflammation, and autoimmunity.[106] PI3K-δ inhibitors are under development for relapsed indolent lymphoma and chronic lymphocytic leukemia.[107]

Nonclinical models utilizing animals either deficient in PI3K-δ and/or PI3K-γ, or treated with inhibitors of these isoforms of PI3K, have established the potential role of PI3K in several inflammatory and autoimmune diseases.[108,109,110] Treatment of mice with inhibitors of PI3K-δ suggests this enzyme is important in the production of antibodies from marginal-zone B cells and peritoneal B1 cells, major sources of autoantibodies in disease. These inhibitors also reduce antigen-specific antibody responses.

Potent inhibitors of PI3K-δ and PI3K-γ enzymes are under development in RA therapy. To date no published data from patients with RA have been published.

## SPHINGOSINE 1 PHOSPHATE MODULATORS

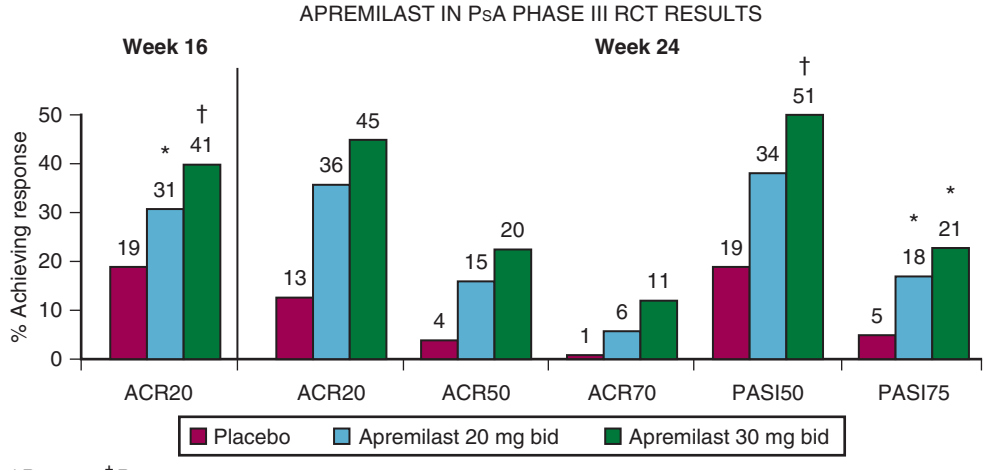
Sphingosine-1-phosphate (S1P) is an abundant, biologically active lysophospholipid. In the immune system, changes in local S1P concentrations and gradients can modify lymphocyte migration patterns, alter inflammatory cell responses, and affect the barrier function of endothelial cells. Interaction of (S1P) with its receptor results in inhibition of lymphocyte egress from primary and secondary lymphoid tissues, resulting in lymphocyte depletion in the peripheral blood. The major and irreversible route of S1P degradation is via S1P lyase (S1PL). Fingolimod, a sphingosine-1-phosphate receptor modulator was approved in 2013 for relapsing-remitting multiple sclerosis.

Pre-clinical studies demonstrated that reduced S1PL activity has a significant effect in reducing the inflammatory response in models of RA.[111,112] LX3305, a small-molecule inhibitor of S1PL, was evaluated as a DMARD. Results of a placebo-controlled, dose-ranging phase II RCT of LX3305

in patients with RA with active disease despite MTX treatment has been reported.[113] In the study, 208 patients received 70 mg, 110 mg, or 150 mg daily, or placebo, for 12 weeks, and the primary endpoint was ACR20 at week 12. Of patients receiving the 150 mg dose, 60% achieved an ACR20 response compared with 49% on placebo, which was not statistically different. Various subanalyses were conducted, suggesting potential benefits, and no significant safety issues were noted. Based on the results of this proof-of-concept study, development in RA was terminated.

## PHOSPHODIESTERASE INHIBITORS

Inhibition of type 4 phosphodiesterase (PDE) has been demonstrated to inhibit TNF production and other pro-inflammatory cytokines.[114,115] Cyclic adenosine monophosphate (cAMP) is the principal second messenger responsible for immune response regulation. PDE4 is the main cAMP-degrading enzyme found in cells of the immune system and keratinocytes. It is the predominant isoenzyme expressed in macrophages, lymphocytes, and neutrophils. Elevation of intra-cellular cAMP inhibits TNF production through the protein kinase A pathway. PDE4 inhibitors are under development for chronic obstructive pulmonary disorder and atopic dermatitis but have not moved forward in development because of gastrointestinal toxicity and possible cardiac toxicity.



Apremilast inhibits production of the pro-inflammatory cytokines, IFN-γ, TNF, IL-12 and IL-23, and inducible nitric oxide synthase.[116] Apremilast was evaluated in RA but did not meet the primary endpoint, and development was terminated in RA. Data from the RA clinical development program have not been published to date.

Apremilast has been approved for the treatment of psoriasis and PsA. Oral administration of apremilast has an absolute bioavailability of 73%, with peak concentration at 2.5 hours (Tmax). The half-life of apremilast is 6 to 9 hours, necessitating twice-daily dosing. Dosages of apremilast at 20 mg twice daily and 30 mg twice daily was evaluated in three multicenter, randomized, double-blind, placebo-controlled trials of 1493 patients with active PsA.[117,118] Patients ranged in age from 18 to 83 years, with an overall median disease duration of 5 years. Patients were randomly assigned to receive either 20 mg twice daily or 30 mg twice daily. Patients with varied subtypes of PsA were enrolled across the three studies, including symmetric polyarthritis (62.0%), asymmetric oligoarthritis (27.0%), distal interphalangeal (DIP) joint arthritis (6.0%), arthritis mutilans (3.0%), and predominant spondylitis (2.1%). Patients received concomitant therapy with at least one DMARD (65.0%), MTX (55.0%), sulfasalazine (SSZ) (9.0%), leflunamide (LEF) (7.0%) and low-dose oral corticosteroids (14.0%), and NSAIDs (71.0%). Prior treatment with non-biologic DMARDs only was reported in 76.0% of patients, and prior treatment with biologic DMARDs was reported in 22.0% of patients, which includes 9.0% who had not responded to prior biologic DMARD treatment. The primary endpoint in the trials was the percentage of patients achieving an ACR20 response at week 16.

ACR responses with apremilast, 30 mg twice daily, were statistically superior to placebo in all three studies (ACR20 response, apremilast, 32% to 41%; placebo, 18% to 19%; $P < 0.05$). ACR50 and ACR70 responses were numerically greater for apremilast, but did not achieve statistical significance (Figure 65-11). The PASI75 response was 21% for apremilast and 5% for the placebo group. The responses for both skin and arthritis are less robust than the responses generally seen with TNF inhibitors.

Diarrhea, headache, and nausea were the most commonly reported adverse reactions. The most common adverse reactions leading to discontinuation were nausea (1.8%), diarrhea (1.8%), and headache. The initial dose is titrated from 10 mg daily to 30 mg twice daily during a period of 5 days to reduce the likelihood of gastrointestinal AEs. The proportion of patients with PsA who discontinued treatment in the trials because of any adverse reaction was 4.6% for patients taking apremilast, 30 mg twice daily and 1.2% for placebo-treated patients.

Warnings in the package insert include the possibility of weight loss and depression. Weight loss of 5 to 10 lb in the

*$P < 0.02$; †$P < 0.0001$

Data from Kavanaugh A, et al: *Ann Rheum Dis* 73(6):1020-1026, 2014.

**Figure 65-11** Apremilast in psoriatic arthritis. ACR, American College of Rheumatology; AE, adverse event; DMARD, disease-modifying anti-rheumatic drug; PsA, psoriatic arthritis.

PsA clinical trials was reported in 10% of apremilast-treated patients and 3.3% of placebo patients. Depression was seen in a small number of patients, but slightly more frequently than in placebo patients.

## CONCLUSION

The unraveling of the intra-cellular pathways involved in signal transduction, resulting in T/B cell activation and inflammatory cytokine production, has resulted in the development of small-molecule inhibitors to these pathways that can abrogate inflammation in inflammatory diseases. Efficacy similar to biologic DMARDs has been demonstrated with an acceptable short-term safety profile. Long-term follow-up of patients on these signal transduction inhibitors is necessary to determine whether these therapies will be safe as a chronic treatment for patients with lifelong disease. Where these new therapies fall into the treatment algorithm for RA has yet to be determined, but they certainly provide an alternative for patients unwilling to pursue parenteral therapies. Newer molecular inhibitors are under development, and we will learn from the ongoing trials whether inhibiting other signaling pathways such as Btk or PI3k will have any additional value for our patients.

CHAPTER 66

# Urate-Lowering Therapy

Ted R. Mikuls

**KEY POINTS**

**Urate-lowering therapy (ULT) is central to the management of hyperuricemia in gout.**

**The goal of ULT in gout is to reduce the frequency of acute flares and prevent progressive joint destruction and tophaceous deposition. This goal can be achieved by lowering and maintaining serum uric acid (UA) below 5 to 6 mg/dL.**

**Optimal ULT requires careful patient selection with attention to comorbid illness, ongoing education, adoption of a treat-to-target approach, and effective anti-inflammatory prophylaxis with treatment initiation.**

Gout is among the most common forms of inflammatory arthritis, affecting almost 4% of the U.S. population with a prevalence exceeding 12% in individuals older than 80 years.[1] The health burden posed by gout is likely to increase: At least one report demonstrates a 44% increase in prevalence in 2007 to 2008 compared with a similar survey conducted in 1988 to 1994.[1] The rapid growth in gout frequency appears to be largely attributable to a near-endemic increase in hyperuricemia. Hyperuricemia is the serum concentration above which uric acid (UA) precipitates into monosodium urate crystals at a physiologic pH of 7.4, defined as serum urate (sUA) levels greater than or equal to 6.8 mg/dL or 405 μmol/L, resulting from renal "underexcretion" in most cases (~80%), with the remainder caused by "overproduction." UA is the end product of purine degradation, with circulating concentrations reflecting the complex interactions of dietary purine intake, endogenous production, and elimination.

The treatment of chronic gout is based primarily on the use of urate-lowering therapy (ULT). Available ULT classes include (1) xanthine oxidase (XO) inhibitors (allopurinol and febuxostat), considered as first-line agents[2]; (2) uricosurics (probenecid, benzbromarone, and sulfinpyrazone); and (3) uricases (pegloticase) (Table 66-1). This chapter focuses primarily on the most common rheumatic indication for ULT, the treatment of hyperuricemia in gout. The optimal use of ULT in gout, regardless of the specific agent used, requires careful consideration of several factors.

## NONPHARMACOLOGIC TREATMENT OF HYPERURICEMIA

The importance of education and lifestyle advice, including weight loss, select dietary restrictions, and reduced alcohol intake, have been emphasized in recent gout management guidelines.[2,3] Despite a growing list of dietary factors implicated in hyperuricemia and gout, investigations of dietary interventions on health outcomes in gout are lacking. Furthermore, evidence suggests that such interventions in isolation yield only modest results and suffer from a lack of widespread patient acceptance and long-term adherence.[4] In addition to dietary modifications that include reducing the intake of dietary purines (particularly those derived from meats and seafood), fructose, beer, and liquor, weight loss represents an important goal for overweight gout patients. Although even modest amounts of weight loss can be important to overall health, resulting reductions in sUA are typically modest[5] and are alone insufficient in many patients with gout. One recent study has shown that more dramatic weight loss in morbidly obese patients with gout can lead to clinically significant reductions in sUA. Among a small group of morbidly obese patients with gout, bariatric surgery resulted in an approximate 25% reduction in mean sUA accompanying an average postsurgical weight loss of 34 kg.[6]

## Patient Selection and Timing of Treatment Initiation

Hyperuricemia should be treated in patients with gout with recurrent and frequent flares, tophi, and/or radiographic changes consistent with gout.[2,3] Although it has long been suggested that ULT should be initiated only after the acute gouty inflammation has resolved with the rationale that its earlier initiation could amplify the duration and magnitude of symptoms, this dogma has recently been challenged. In a randomized controlled study of 57 men with crystal-proven gout, allopurinol initiation during an acute flare resulted in no differences in self-reported pain or the occurrence of recurrent gout attacks compared with placebo when administered with background anti-inflammatory agents.[7] Conversely, the development of a gout flare that complicates ongoing ULT is not an indication to discontinue or postpone ULT. Results from a cost-effectiveness analysis in nontophaceous gout, involving a hypothetical patient cohort, suggest that the institution of allopurinol is cost effective in patients seen with two or more acute gout flares within a 1-year period.[8] Although there has been substantial speculation regarding the potential role of ULT in cardiovascular disease prevention and the treatment of hypertension, available ULTs are not

**TABLE 66-1** Dosing and Safety Information for Currently Available Urate-Lowering Therapies in the Management of Gout

| | Dose | Route/ Schedule | Half-life | Primary Site of Metabolism/ Elimination | Adverse Effects | Contraindications (C)/Drug Interactions (DI) |

| **Xanthine Oxidase Inhibitors** | | | | | | |
| Allopurinol | 100-800 mg | PO/daily | 1-2 hr (half-life of active metabolite oxypurinol 15-30 hr) | Met: Hepatic xanthine oxidase and aldehyde oxidase (into oxypurinol)<br>Elim: Renal (renal dosing may be required) | Common: Gout flare; skin rash; nausea; diarrhea; LFT abnormalities<br>Rare: Allopurinol hypersensitivity syndrome (AHS) (more common in HLA-B*5801+); cytopenias | C: Concomitant azathioprine, 6-MP, theophylline, prior hypersensitivity<br>DI: Azathioprine, 6-MP, theophylline, ampicillin/ amoxicillin, uricosurics, thiazides, cyclosporine, warfarin, ACE inhibitors (possible), Dilantin, cyclophosphamide, vidarabine |
| Febuxostat | 40-120 mg | PO/daily | 6-8 hr | Met: Hepatic (glucuronyl conjugation and oxidation via Cyt P450)<br>Elim: Hepatic and renal | Common: Gout flare; skin rash; nausea; arthralgias; LFT abnormalities<br>Rare: Cardiovascular events (unclear association); cytopenias | C: Concomitant azathioprine, 6-MP, theophylline, prior hypersensitivity; severe hepatic impairment<br>DI: Azathioprine, 6-MP, theophylline |
| **Uricosurics** | | | | | * Adverse effects, contraindications, drug interactions similar for available uricosurics—grouped together below | |
| Probenecid | 500-2000 mg | PO/bid | 3-8 hr (500 mg); 6-12 hr (larger doses) | Met: Hepatic (hydroxylation)<br>Elim: Hepatic and renal | Common: Gout flare; nephrolithiasis; rash; flushing; nausea; loss of appetite<br>Rare: Cytopenias, nephrotic syndrome, anaphylaxis, back pain (rare reports of hepatotoxicity with benzbromarone) | C: Prior hypersensitivity; nephrolithiasis; UA overexcretion; concomitantly with other cancer therapies; known blood dyscrasias; active peptic ulcer disease; sulfinpyrazone should be avoided in patients with phenylbutazone/pyrazole allergy<br>DI (more extensive for probenecid/sulfinpyrazone then benzbromarone): allopurinol, NSAIDs, salicylates, penicillins, cephalosporins, fluoroquinolones, imipenem, rifampin, nitrofurantoin, sulfonamides, heparin, dapsone, acyclovir, ganciclovir, zidovudine, alcohol, diazoxide, mecamylamine, pyrazinamide, antineoplastic agents, clofibrate; dyphylline, diuretics, benzodiazepines, methotrexate, riboflavin, thiopental |
| Sulfinpyrazone | 200-800 mg | PO/bid | 3-12 hr | Met: Hepatic (CYP2C9)<br>Elim: Hepatic and renal | | |
| Benzbromarone | 50-200 mg | PO/daily | 3 hr (half-life of active metabolite 6-hydroxybenzbromarone ~30 hr) | Met: Hepatic (CYP2C9)<br>Elim: Hepatic and renal | | |
| **Uricases** | | | | | | |
| Pegloticase | 8 mg* | IV/every 2 wk | Highly variable (days to wk) | Not well defined | Common: Gout flare; allergic reactions; anaphylaxis (~7%); infusion reactions (urticaria, dyspnea, chest discomfort, pruritis, chest discomfort)<br>Rare: CHF exacerbation (unclear association) | C: Allergic reactions to medication or loss of effect (serum UA >6.0 mg/dL indicates development of antipegloticase antibody)<br>DI: Other PEGylated agents (possible) |

*Pre-dosing with fexofenadine 60 mg, acetaminophen 1000 mg, and hydrocortisone 200 mg IV on the day of the infusion.

ACE, Angiotensin-converting enzyme; bid, twice daily; CHF, congestive heart failure; Cyt, cytochrome; Elim, elimination; HLA, human leukocyte antigen; IV, intravenous; NSAIDs, nonsteroidal anti-inflammatory drugs; PEGylated, polyethylene glycosylated; PO, by mouth; tid, three times daily; UA, uric acid .

currently approved for the treatment of hyperuricemia in the absence of gout.

## Duration of Urate-Lowering Therapy

In asymptomatic patients with gout successfully treated with prior ULT, withdrawal of therapy often results in an abrupt increase in sUA, with recurrent attacks occurring in approximately one-third of patients within two years.[9] Similarly, reductions from continuous ULT to an "intermittent" regimen in previously stable patients with gout lead to significantly higher flare rates,[10] whereas ULT discontinuation in the setting of tophaceous gout leads to recurrent gout flares in a vast majority and recurrent tophi in nearly half.[11] Taken together, these reports suggest that ULT should be "lifelong" in patients with gout.

## Target Serum Urate Goals

Lowering and maintaining sUA less than 6.0 mg/dL (<360 μmol/L) leads to improved long-term outcomes in gout, a treatment goal advocated in management guidelines[2,3] with recent recommendations suggesting that an even lower target goal (<5.0 mg/dL or <300 μmol/L) may be needed to control the disease in some patients, including those with tophi.[2] ULT reduces the long-term risk of recurrent flare by approximately 60% for each 1 mg/dL decrease in sUA.[12] Additional evidence suggests that reaching and maintaining sUA concentrations less than 6.0 mg/dL is important for the depletion of total body urate stores.[13] It is important to recognize that these target goals often fall well below the upper-limit normal for sUA in clinical laboratories that define ranges based on population-based distributions.

## Anti-inflammatory Prophylaxis with Urate-Lowering Therapy Administration

Rebound gout flare is the most common complication of ULT regardless of the agent used, rendering anti-inflammatory prophylaxis a key component of successful gout treatment.[2,3] Gout flares complicating ULT are thought to be caused by reduced sUA concentrations that result in the mobilization of monosodium urate crystals from articular and periarticular deposits into joints. The frequency of treatment-related gout flares appears to be higher with more rapid and potent urate-lowering interventions.[14] Both colchicine and nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in reducing gout flares during ULT initiation.[15-17] Although low-dose glucocorticoids (e.g., prednisone or prednisolone equivalent of ≤10 mg daily) are commonly used in this context, data supporting their use are limited. Results from Borstad and co-workers.[16] suggest that anti-inflammatory prophylaxis with low-dose oral colchicine (0.6 mg, twice/day) protects against rebound gout flares and may need to be continued for at least 6 months after ULT initiation. Frequently used in gout flare prevention, the efficacy of low-dose glucocorticoids in this setting has not been well defined. Under active investigation, agents targeting interleukin (IL)-1, including both canakinumab and rilonacept, have demonstrated preliminary efficacy in the prevention of gout flare complicating ULT initiation.[18,19]

### Urate-Lowering Therapy Adherence

Suboptimal treatment compliance poses a major obstacle to effective ULT, with reports consistently demonstrating rates of medication adherence of 50% or less in gout.[20,21] Treatment adherence in gout was recently shown to be the lowest of seven different chronic conditions examined,[20] emphasizing again the importance of patient education in disease management.

# XANTHINE OXIDASE INHIBITION

## Allopurinol

**KEY POINTS**

- **Advantages of allopurinol over the most commonly used uricosurics include its once-daily dosing, effectiveness in both "underexcretors" and "overproducers," and its potential effectiveness in patients with renal insufficiency.**
- **Allopurinol hypersensitivity syndrome (AHS) is a relatively uncommon, albeit potentially serious, adverse event associated with its use.**
- **Allopurinol doses higher than 300 mg/day are frequently required to achieve target sUA goals; evidence and consensus-based gout treatment guidelines recommend the initial use of low-dose allopurinol (≤100 mg/day) with gradual increases in dosing to achieve target sUA goals.**

Available for approximately 50 years, allopurinol accounts for a vast majority of all ULT prescriptions.[22] In addition to its established track record in gout, allopurinol has several advantages: (1) low cost, (2) once-daily oral administration, (3) effectiveness in patients who underexcrete and those who overproduce UA, (4) favorable safety profile, and (5) potential effectiveness in patients with renal impairment. Allopurinol treatment results in significant declines in sUA,[17,23,24] decreased gout flare rates,[17,23-30] and declines in tophus area.[23]

### Role in Rheumatic Disease and Indications

Approved indications for allopurinol include (1) treatment of hyperuricemia in gout, (2) the management of hyperuricemia resulting from the treatment of malignancy (most often leukemia or lymphoma), and (3) the management of nephrolithiasis in the context of increased urinary UA excretion. Although not approved for the treatment of asymptomatic hyperuricemia in the absence of gout, there is evidence suggesting that allopurinol use may have other health benefits. Hyperuricemia is independently associated with cardiovascular morbidity and mortality,[31-34] giving rise to speculation that ULT could be cardioprotective.[35] At least two prospective studies have shown a lower all-cause mortality risk among individuals receiving allopurinol,[35,36] although it was not clear from these investigations whether this benefit was mediated by reductions in cardiovascular risk. In a placebo-controlled study of pediatric essential hypertension, allopurinol use resulted in significant, albeit modest, declines in blood pressure.[37] XO inhibition via allopurinol also has been shown to improve endothelial

function, improving measures of both local and systemic blood flow[38] and has been associated with improvements in renal function in at-risk populations.[39,40]

## Chemical Structure and Mechanism of Action

An antimetabolite in simple organisms, allopurinol inhibits XO (Figure 66-1), a key enzyme in purine catabolism, but does not inhibit the biosynthesis of purines in humans.

## Pharmacology

Pharmacologic characteristics of the ULTs are summarized in Table 66-2. Allopurinol is approximately 90% absorbed from the gastrointestinal (GI) tract and is metabolized into oxypurinol, its active metabolite. Peak serum concentrations for allopurinol and oxypurinol are achieved within approximately 1 to 2 hours and 4 to 5 hours, respectively. The plasma half-life of allopurinol is relatively brief (1 to 2 hours) although the half-life of oxypurinol is substantially longer (~15 hours or longer), allowing for once-daily dosing. Allopurinol is eliminated primarily via glomerular filtration, whereas oxypurinol undergoes some degree of renal tubular reabsorption. With renal mechanisms primarily responsible for drug elimination, the plasma half-life of allopurinol, and to a greater degree oxypurinol, are increased with renal insufficiency.

**TABLE 66-2** Agents Not Approved for Gout Treatment That Display Urate-Lowering Properties

| Agent | Usual Indication |
|---|---|
| Losartan | Hypertension, congestive heart failure |
| Fenofibrate | Hyperlipidemia, hypertriglyceridemia |
| Atorvastatin | Hyperlipidemia |
| Rosuvastatin | Hyperlipidemia |
| Guaifenesin | Upper respiratory airway congestion |
| Leflunomide | Rheumatoid arthritis |
| Salicylates (high dose) | Analgesia, fever, anti-inflammatory |

## Dose and Drug Administration

Allopurinol is available as 100 mg and 300 mg pills for once-daily oral administration (see Table 66-2), with split dosing advocated in some instances for daily doses 600 mg or higher. Used in the treatment and/or prevention of tumor lysis syndrome, allopurinol is available intravenously. Approved at daily doses as high as 800 mg in the United States and 900 mg in Europe, allopurinol is rarely administered at doses exceeding 300 mg/day in everyday clinical practice,[41] although greater doses are often required to appropriately manage the signs and symptoms of gout. It is well established that only a modest proportion of patients achieve a target sUA less than 6.0 mg/dL with allopurinol 300 mg/day, the most commonly used dose. With a target sUA threshold of less than 5.0 mg/dL, investigators have shown that only one-fourth of patients with gout achieve this goal with 300 mg of daily allopurinol, a proportion that increased to 78% with a daily dose of 600 mg.[42] The limitation of "standard" dose allopurinol has been proved in randomized clinical trials that have compared fixed daily doses of 300 mg with febuxostat in various doses. In those studies, approximately 40% of allopurinol-treated patients with gout achieved a final sUA less than 6.0 mg/dL.[17,23] Recent gout treatment guidelines recommend that allopurinol be started in low doses (e.g., 100 mg daily) and increased by 100 mg every 2 to 5 weeks as required to achieve the target.[2,3] Data from two studies suggest that each 100 mg increase in allopurinol leads to an additional decline in sUA approaching 1.0 mg/dL.[43,44] Implementing a "start low and go slow" approach and other key elements of proposed "best

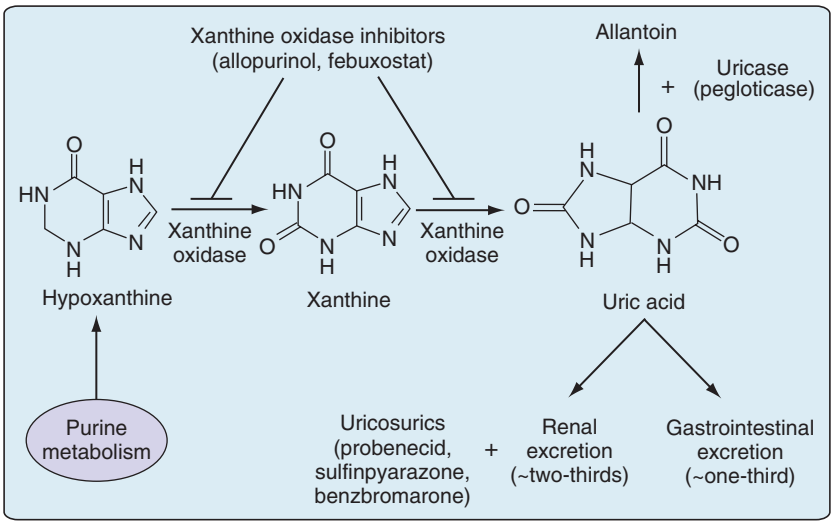

**Figure 66-1** Endogenous synthesis and elimination of uric acid (UA). UA is the end product of purine degradation in humans. Xanthine oxidase (XO), which converts hypoxanthine to xanthine and xanthine to UA, is a rate-limiting enzyme in this process, and is targeted by select urate-lowering therapies in gout treatment, including allopurinol and febuxostat. Although humans do not express a functional form of uricase, other mammalian species are able to catalyze the conversion of UA into allantoin, which is far more soluble. Recombinant forms of uricase, including pegloticase, have been developed for use in treatment failure gout. UA in humans is eliminated primarily in the kidneys. Renal excretion of UA is enhanced through uricosuric administration.

practices."[2,3] investigators recently reported a 92% success in achieving sUA treatment goals in gout.[45] Among those receiving allopurinol, the most commonly used ULT in the study, patients who achieved the target required a median daily dose of 400 mg.[45]

There is general consensus that *initial* allopurinol dosing should be adjusted for diminished renal function,[3,46,47] which prolongs the plasma half-life of oxypurinol. Commonly cited dosing algorithms suggest administering an initial daily dose of 100 mg or less for patients with a glomerular filtration rate (GFR) below 20 mL/min, with even lower doses for those with more severe renal impairment.[48] Whether existing dosing guidelines preclude the use of incremental dosing beyond these recommended renal thresholds has been the subject of debate. The standard recommended renal dosing guidelines[48] are not evidence based and are founded largely on a single retrospective case series showing that patients in whom allopurinol hypersensitivity syndrome (AHS) developed were more likely to have renal insufficiency. Indeed, of patients with chronic kidney disease (CKD) in whom AHS developed, many received "appropriately" dosed allopurinol.[49,50] In a review of 120 patients with gout receiving allopurinol, more than half (57%) required titration of daily doses higher than the "renal threshold" recommended by Hande,[48] a strategy that was well tolerated in the vast majority of patients.[51]

### Toxicity

AHS is an uncommon but potentially fatal treatment complication with approximately 90% of cases occurring within 60 days of allopurinol initiation.[52] AHS is characterized by the presence of an erythematous desquamating rash (similar to Stevens-Johnson syndrome), fever, eosinophilia, and end-organ damage, including hepatitis and renal failure.[48] AHS complicates as many as 0.1% to 0.4% of allopurinol treatment courses, although rates have been estimated to be as low as 1 in 56,000 allopurinol users.[53] In addition to its association with higher initial allopurinol doses,[54] AHS appears to be substantially more common in individuals positive for *HLA-B*5801*. In a small Taiwanese case-control study, all patients in whom AHS developed were positive for *HLA-B*5801*, compared with only 15% of allopurinol-treated patients without AHS.[55] This risk allele is present in approximately 2% to 7% of Caucasians, 7% of Africans, and 8% or more of Asian Indians.[56] With genetic assays commercially available, testing for *HLA-B*5801* has been proposed to be cost effective and even cost saving when implemented in high-risk populations,[57] such as Korean patients with CKD and all individuals of Han Chinese or Thai descent.[2] It has been estimated that the use of appropriately low starting doses, adjusted for renal function, may by itself reduce AHS risk by approximately 10-fold.[54] Given the potential severity of AHS, patients should be educated about the remote possibility of this adverse event and cautioned to discontinue allopurinol if a rash develops, particularly if accompanied by fever or mucocutaneous lesions.

Recognizing the rare occurrence of AHS, allopurinol is generally well tolerated. Estimates suggest that less than 5 to 10% of those exposed are intolerant to the drug.[58] Rebound flares are among the most common complication that accompanies allopurinol and other ULT, an issue that is most prominent in the early phases of drug initiation and can be mitigated by anti-inflammatory prophylaxis. Isolated maculopapular skin rash can occur outside the context of AHS and is estimated to complicate approximately 1% to 3% of allopurinol treatment courses. Other common adverse events associated with allopurinol use are summarized in Table 66-1. Liver function abnormalities can be seen in approximately 6% to 7% of allopurinol users,[24] although rates of severe liver injury appear to be exceedingly low. The role and recommended frequency for laboratory surveillance in toxicity monitoring has not been well defined.

### Fertility, Pregnancy, and Lactation

Recognizing that there have been no human studies of its use in pregnancy,[59] allopurinol is classified as a Pregnancy Category C agent (animal reproduction studies have shown an adverse effect on fetus without adequate human studies). Both allopurinol and oxypurinol are expressed in breast milk, and because drug effects in the developing infant are largely unknown, it should be administered to a nursing mother with caution.

### Drug Interactions and Contraindications

Allopurinol drug interactions have been well characterized. Azathioprine and 6-mercaptopurine (6-MP) are metabolized primarily by XO, hence co-administration of allopurinol leads to marked increases in circulating drug levels that can lead to bone marrow suppression.[60-62] Theophylline is also metabolized by XO, and therefore co-administration of this agent with allopurinol can lead to increased theophylline levels and potentiate toxicity. The co-administration of allopurinol with ampicillin/amoxicillin has been associated with a higher incidence of drug-related rash.[63] Thiazide diuretics may also reduce the renal excretion of allopurinol and oxypurinol with suggestions that this could potentiate drug-related toxicity, including the risk of AHS.[64] Uricosurics increase the renal excretion of oxypurinol, thus offsetting to some degree the urate-lowering effect of allopurinol.[65] Allopurinol co-administration may increase drug levels of cyclosporine and warfarin, mandating close monitoring of drug levels and bleeding parameters, respectively. Other allopurinol-associated drug interactions are summarized in Table 66-1. Although regimens for desensitization have been described, allopurinol should be avoided in patients with known allergies to allopurinol, including AHS.

## FEBUXOSTAT

**KEY POINTS**

**Febuxostat is a potent inhibitor of xanthine oxidase (XO), with a chemical structure that is distinct from that of allopurinol.**

**Febuxostat represents an important alternative to patients for whom allopurinol is not effective, either because of intolerance or lack of efficacy.**

Febuxostat is a potent and selective inhibitor of XO that is structurally distinct from allopurinol.

## Role in Rheumatic Diseases and Indications

Febuxostat is approved for the treatment of hyperuricemia in patients with gout. Similar to other ULTs, febuxostat is not indicated for the treatment of asymptomatic hyperuricemia. Given its unique structure, febuxostat represents an important alternative means of XO inhibition, particularly in patients with gout who are intolerant to allopurinol.[58] The role of febuxostat in gout management was previously addressed by an international panel, providing guidance specific to indications, contraindications, monitoring, and issues requiring future research.[66] Because of its urate-lowering effect, febuxostat is thought to exert potential benefits beyond the treatment of gout, with at least one study demonstrating improvements in vascular function[67] in patients with tophaceous gout. Another planned study will examine the agent's utility in preventing further reductions in renal function in patients with CKD.[68]

### Chemical Structure and Mechanism of Action

In contrast to allopurinol, febuxostat is a nonpurine analog that reduces serum and urinary urate concentrations through selective XO inhibition (see Figure 66-1). In contrast to allopurinol, which may inhibit other enzymes involved in purine and pyrimidine synthesis, febuxostat demonstrates significant enzymatic inhibition only for XO at therapeutic concentrations.[69]

### Pharmacology

After oral administration, febuxostat is rapidly absorbed from the GI tract with approximately 50% absorption, reaching peak plasma concentrations within a few hours[70] with near-complete plasma protein binding (see Table 66-1). Febuxostat displays linear pharmacokinetics that are not time dependent, with drug metabolism occurring primarily in the liver through conjugation via uridine diphosphate glucuronosyltransferase and oxidation via cytochrome P450 enzymes.[70] Peak urate-lowering effects with febuxostat generally occur during the first 5 to 7 days of treatment. Drug elimination occurs via both hepatic and renal pathways. Although active metabolites are produced via oxidation, these are present in much lower plasma concentrations.

### Dose and Drug Administration

Febuxostat is available in 40 mg tablets in the United States, in 80 mg tablets doses in the United States and Europe, and 120 mg tablets doses in Europe for oral administration. The usual dosing ranges from 40 mg to 120 mg daily (see Table 66-1). Febuxostat should be initiated at a lower dose (40 mg to 80 mg daily) and increased to higher doses (80 mg to 120 mg daily) if sUA levels remain higher than 6.0 mg/dL after 2 weeks. In a phase II study, sUA levels less than 6.0 mg/dL were obtained by 56%, 76%, and 94% of patients receiving 40 mg, 80 mg, and 120 mg/day of febuxostat, respectively, compared with 0% for placebo.[14] Mean sUA reductions were greater with higher daily doses, ranging from a 37% reduction in the 40 mg/day group to 59% in the 120 mg/day group. Two subsequent trials lasting 28 weeks ($n = 1067$)[17] and 52 weeks ($n = 762$)[15] compared febuxostat (80 mg to 240 mg/day) with fixed-dose allopurinol (300 mg daily) with both trials by using the primary outcome of a sUA less than 6.0 mg/dL at the last three consecutive monthly observations. The primary endpoint was achieved by 48% to 53%, 62% to 65%, and 69% of patients with gout receiving daily doses of 80 mg, 120 mg, and 240 mg, respectively, compared with 21% to 22% of patients receiving fixed-dose allopurinol. Secondary outcomes in the trial by Becker and co-workers.[15] showed declines in both gout flare rates and an approximately 70% to 80% reduction in gout tophus area during follow-up. These findings were not significantly different from those observed with allopurinol. Studies of febuxostat[15,17,24] to date have used fixed-dose allopurinol (≤300 mg/day) as an active comparator. As detailed previously, current gout treatment guidelines recommend initiating low-dose allopurinol (i.e., 100 mg/day) with incremental dosing as needed to achieve target urate thresholds.[3,46] Because optimal allopurinol dosing strategies were not used in these studies, these results almost certainly overestimate the incremental effectiveness of febuxostat relative to optimally dosed allopurinol.

Metabolized primarily in the liver, febuxostat may not require renal dosing.[71] This receives support from a few small short-term pharmacokinetic studies that included a limited number of patients with renal impairment.[72,73] There are insufficient data from longer-term studies of febuxostat in patients with moderate renal impairment (serum creatinine of ~1.6 to 2.0 mg/dL) and essentially no data from patients with more severe renal dysfunction (serum creatinine >2.0 mg/dL). Available data, albeit limited, suggest that those with mild or moderate renal impairment (estimated creatinine clearance [Cr CL] between 30 and 90 mL/min) experience similar efficacy and similar rates of toxicity compared with those with preserved renal function receiving the same doses of febuxostat.[15,24]

### Toxicity

Similar to other ULTs, rebound gout flares are the most common complication of febuxostat administration, underscoring the importance of anti-inflammatory prophylaxis.[14] Other adverse reactions observed with febuxostat are summarized in Table 66-1, adverse effects that appear to occur at similar rates to those observed with allopurinol.[24,70] In initial studies comparing febuxostat with allopurinol, there was a slightly higher rate of cardiovascular events in patients receiving febuxostat (0.74 events per 100 patient-years; 95% CI, 0.36 to 1.37) compared with those randomly assigned to allopurinol (0.60 events per 100 patient; 95% CI, 0.16-1.53).[70] In the large 6-month CONFIRMS trial, investigators found no differences in the rates of cardiovascular events between patients treated with febuxostat (40 mg and 80 mg/day) and allopurinol (200 mg to 300 mg/day), recognizing the limited power of this study with only six adjudicated events occurring during follow-up.[24] Large studies are currently underway that will compare the cardiovascular safety of febuxostat versus allopurinol during extended follow-up.[74,75]

Because of its unique structure and select XO inhibition, it has been suggested that febuxostat may represent a

rational alternative for patients with gout with a history of allopurinol hypersensitivity. Whether febuxostat can be effectively administered in such patients is not clear, given post-marketing reports of hypersensitivity in patients given febuxostat. In a small retrospective study involving 13 patients with gout with a history of severe allopurinol-related adverse reactions, 12 were subsequently treated safely with febuxostat (10 achieved target sUA goals).[76] A hypersensitivity vasculitis of the skin developed in a single patient.

### Fertility, Pregnancy, and Lactation

The effects of febuxostat on fertility are not known. Likewise, there have been no studies of febuxostat in pregnant women although results from animal studies have not suggested a significant risk of teratogenicity.[70] However, in the absence of appropriate human studies, febuxostat is labeled as Pregnancy Category C. It is not known whether the drug is excreted in human milk and febuxostat should be used only with caution in nursing women, because its effects in developing infants are unknown.

### Drug Interactions and Contraindications

Although formal drug-interaction studies have not been performed, febuxostat should be used with caution with drugs that are metabolized by XO (azathioprine, 6-MP, theophylline) (see Table 66-1). Its use should be avoided in patients with prior hypersensitivity to febuxostat. Because of hepatic metabolism, febuxostat should not be used in patients with moderate to severe liver impairment.[66]

## URICOSURICS

**KEY POINTS**

- **Probenecid, sulfinpyrazone, and benzbromarone are the most common uricosuric agents used in gout treatment worldwide.**
- **Although often requiring twice-per-day to three-times-per day dosing, uricosurics are potentially effective in lowering sUA in patients who underexcrete uric acid, the most common pathologic defect leading to hyperuricemia.**
- **Probenecid and sulfinpyrazone may have limited efficacy in the context of moderate to severe renal insufficiency.**

Uricosurics represent the first class of ULT to be used in gout treatment.[77] A complex system of renal handling of urate has been proposed that sequentially includes four components[78]: (1) near-complete glomerular filtration, (2) proximal reabsorption, (3) tubular urate secretion occurring more distally, and (4) reabsorption for a second time more distally. Available uricosurics diminish the postsecretory reabsorption of UA, therefore promoting its elimination and reducing sUA. Uricosurics address the most common physiologic defect in gout, UA underexcretion. In addition to promoting renal UA excretion, uricosurics may inhibit the tubular secretion of a number of other compounds, including penicillins. Although many agents display uricosuric properties, the most commonly used uricosurics in gout worldwide are probenecid, sulfinpyrazone, and benzbromarone. Probenecid is the most widely used uricosuric in gout treatment. Primarily because of concerns of treatment-related toxicity, sulfinpyrazone and benzbromarone are less widely available, and neither is available in the United States.

Although the focus of this section is on "primary" uricosurics, there are several medications approved for the treatment of nongouty conditions that exert uricosuric effects. "Secondary" uricosurics and their indications are summarized in Table 66-2.[79-84] Salicylates exert a paradoxical effect on renal urate elimination, with the inhibition of active secretion with lower doses (e.g., <1 g/day) and a "uricosuric-like" inhibition of UA reabsorption at higher doses (>4 to 5 g/day). Along with salicylates, losartan has perhaps been most closely scrutinized for its hypouricemic properties, an effect that is mediated via inhibition of URAT1 and appears to be specific to this angiotensin receptor blocker.[80] The magnitude of sUA lowering that can be achieved with these "secondary" hypouricemics is modest. Losartan used at an anti-hypertensive dose of 50 mg/day resulted in mean sUA declines of approaching 9%.[80] It is important to recognize that the urate-lowering effect of losartan appears to be negated when co-administered with hydrochlorothiazide,[85] a combination used in hypertension treatment.

### Role in Rheumatic Disease and Indications

Probenecid, sulfinpyrazone, and benzbromarone are used to treat hyperuricemia associated with gout and are indicated in patients with gout who underexcrete UA (24-hour urine UA, <700 mg). Probenecid is also approved as an adjuvant to penicillin therapy, increasing plasma concentrations and prolonging the terminal half-life of penicillin and other penicillin derivatives. Although potentially effective for a majority of patients with gout, uricosurics are much less commonly used than allopurinol and have been designated as second-line ULTs in gout management guidelines.[2] In a population-based study from the United Kingdom, uricosuric therapy accounted for less than 5% of all ULT prescriptions.[22]

### Mechanism of Action

Uricosurics work primarily through the inhibition of the renal tubular urate-anion exchanger, URAT1 (SLC22A12) in addition to GLUT9 (SLC2A9) (Figure 66-2). Thus uricosurics reduce UA reabsorption, promote renal elimination, and decrease sUA.[86-90]

### Pharmacology

Administered orally, uricosurics undergo GI absorption and are extensively protein bound in the serum. Half-lives of probenecid[91] and sulfinpyrazone[92] are relatively brief, ranging from approximately 3 to 12 hours (see Table 66-1). Although benzbromarone also has a relatively short half-life of approximately 3 hours, its active metabolite 6-hydroxybenzbromarone has a much longer half-life, allowing for effective once-daily administration.[93] Elimination of the uricosurics is primarily via hepatic metabolism,

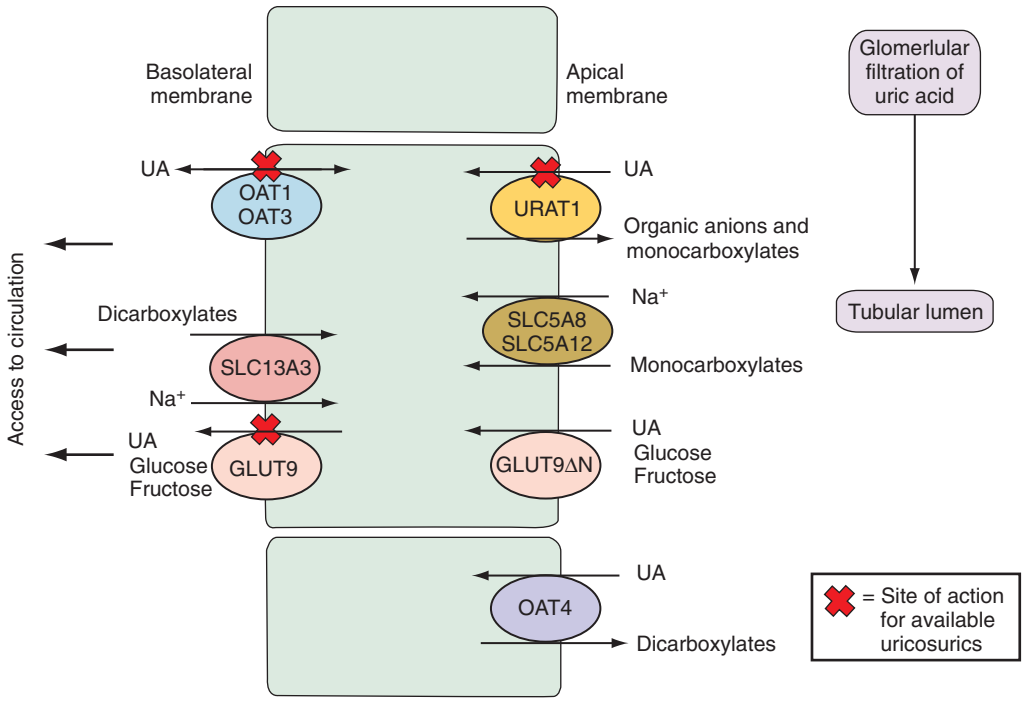

**Figure 66-2** Renal handling of uric acid (UA) and sites of action for available uricosurics, including probenecid, sulfinpyrazone, and benzbromarone in the proximal renal tubule. Serum UA undergoes near complete glomerular filtration. UA reabsorption is then mediated primarily by URAT1 and GLUT9 transporters in the proximal tubule, reabsorption that is inhibited by available uricosurics. Tubular reabsorption of UA requires sodium ($Na^+$)-dependent loading of monocarboxylates and dicarboxylates, which are subsequently exchanged with UA via URAT1 (monocarboxylates) and organic anion transporter (OAT)-4 (dicarboxylates). Monocarboxylates include lactate, pyruvate, acetoacetate, hydroxybutyrate, and acetate. Dicarboxylic acids include oxalic acid, malonic acid, and succinic acid, among others. In addition to facilitating UA exchange, GLUT9 mediates the reabsorption of glucose and fructose. RDEA 594 is an investigational uricosuric that appears to inhibit URAT1 specifically, whereas tranilast (also an investigational agent) inhibits both URAT1 and GLUT9 transporters *(Modified from Dalbeth N, Merriman T: Crystal ball gazing: new therapeutic targets for hyperuricaemia and gout.* Rheumatology [Oxford] *48:222-226, 2009, with permission.)*

followed by variable excretion of metabolites in the urine, bile, and/or feces. The metabolism of probenecid is limited to side-chain hydroxylation, *N*-depropylation, and glucuronic conjugation of its carboxyl group.[94-96] Both sulfinpyrazone and benzbromarone are metabolized via cytochrome P450 (CYP), with CYP2C9 representing a principal mediator.[97,98] Warfarin is also metabolized by primarily via CYP2C9, explaining its drug-drug interactions with both sulfinpyrazone and benzbromarone.

## Dose and Drug Administration

Usual probenecid dosing is 500 to 2000 mg daily in divided doses. Probenecid (500 mg) is also formulated with colchicine (0.5 mg) as a combination tablet (col-probenecid). In a 12-week randomized study involving patients with preserved renal function, probenecid, 1500 mg/day was associated with a 32% reduction in plasma urate concentration,[99] with older studies documenting other qualitative benefits of therapy, including softening of tophi, functional improvement, and improved pain symptoms.[29,100] Sulfinpyrazone is given in divided doses at an initial daily dose of 200 to 400 mg, increasing to 800 mg daily, if necessary to achieve target sUA goals. Although there is no level of renal function below which probenecid and sulfinpyrazone are known to completely lose efficacy,[53] these drugs may lose effectiveness in patients with moderate to severe renal insufficiency.[101] In a retrospective study of 57 patients with gout, probenecid yielded moderate efficacy as a ULT with baseline sUA, but not renal function per se, predicting treatment response.[102] In contrast to common dogma, these results suggest that probenecid can be used effectively in select patients with mild to moderate CKD.

Benzbromarone is administered once daily and may be effective in patients with moderate renal impairment. Benzbromarone treatment in usual doses (50 to 200 mg/day) leads to between 25% and 50% reductions in sUA[103-106] in addition to decreases in gout flare rates and tophi.[107-109] In a randomized controlled trial, benzbromarone maintained its hypouricemic effect even among patients with a Cr CL as low as 20 to 40 mL/min.[106] Among patients intolerant to or experiencing treatment failure with allopurinol 300 mg/day, 92% of those administered benzbromarone (200 mg/day) achieved a sUA less than 5.0 mg/dL compared with 65% of those receiving probenecid (2000 mg/day).[110]

Uricosurics may also serve as effective adjuvants to XO inhibition. Although uricosurics enhance oxypurinol excretion, the active metabolite of allopurinol, the effect on oxypurinol clearance[65] does not appear to negate the additive urate-lowering effect gained by using these medications in combination. Among patients failing allopurinol monotherapy (200 to 300 mg/day), 86% achieved a target sUA of less than 5 mg/dL after the addition of probenecid (1000 mg/day).[111] Likewise, the combination of

benzbromarone and allopurinol has been shown to have a more potent urate-lowering effect than allopurinol alone, and the combination has been shown to yield a more rapid resolution of tophi than allopurinol monotherapy.[109]

### Toxicity

As with other ULTs, rebound gout flares represent a common complication of uricosurics. Because urinary UA acts as a potential nidus for stone formation, uricosuric therapy is associated with an increased risk of nephrolithiasis. In a longitudinal study including more than 780 patient-years of benzbromarone exposure, nephrolithiasis developed in approximately 10% (21 of 216 patients).[112] Of the 21 patients with incident nephrolithiasis, oxalate stones developed in 7 patients, and stones composed of either UA or a combination of UA and calcium developed in 14 patients. In addition to limiting uricosurics to patients who underexcrete UA, the risk of treatment-related nephrolithiasis can be mitigated by optimizing fluid intake and alkalinizing the urine with a goal of maintaining a urine pH higher than 6.0.[113] Other adverse effects observed with uricosurics are summarized in Table 66-1. Rare adverse effects include anaphylaxis, anemia (including aplastic and hemolytic anemia), other cytopenias, fever, nephrotic syndrome, and back pain. Rare reports of severe liver injury led to the withdrawal of benzbromarone by its primary manufacturer in 2003, a decision recently challenged in systematic risk-benefit analysis of the drug.[53] Because of its NSAID-like properties, sulfinpyrazone has been associated with an increased frequency of blood dyscrasia (rare) in addition to upper GI disturbances including peptic ulcer disease.[114]

### Fertility, Pregnancy, and Lactation

There are limited data regarding the impact of uricosurics on fertility, fetal development, and use with nursing infants; thus these agents should be used with caution in such patients only when the potential benefits of treatment outweigh its potential risks.

### Drug Interactions and Contraindications

With the knowledge that tubular secretion plays a central role in the renal clearance of numerous drugs, drug-drug interactions with the use of uricosurics, particularly probenecid, are well-known (see Table 66-1). Inhibition of tubular drug secretion appears to be greater for probenecid and sulfinpyrazone than benzbromarone due to the increased URAT1 "specificity" of the latter agent. Drug interactions observed with uricosurics are summarized in Table 66-1.

As with all ULTs, the uricosurics should not be initiated during an acute gout flare and should not be used in patients with known allergies to these agents. Because of the potential for cross-reactivity, sulfinpyrazone should be avoided in patients with allergies to phenylbutazone or other pyrazole compounds. Except under special circumstances, these agents should be avoided in patients with nephrolithiasis, evidence of UA overexcretion, and during cancer treatment including chemotherapy and/or radiation. Caution should also be used in patients with known blood dyscrasias, active peptic ulcer disease, and/or significant hepatic or renal disease.

## URICASES

### Pegloticase

**KEY POINTS**

- **Pegloticase facilitates the conversion of UA into allantoin; the latter is far more soluble.**
- **The intravenous administration of pegloticase is associated with rapid and marked declines in sUA, which may be particularly important in the rapid depletion of total-body urate levels.**
- **Antigenicity and an immune response directed towards the drug are major limitations in the repeated dosing of pegloticase.**

Pegloticase, a modified mammalian uricase, is a biologic parenterally administered agent and represents the most recently approved ULT in gout. Unlike other mammalian species, humans have lost the ability to synthesize functional uricase that converts UA into allantoin, the latter 5 to 10 times more soluble. The use of alternative uricases (e.g., rasburicase, a recombinant uricase from *Aspergillus flavus*[115]) in the treatment of tumor lysis syndrome has been substantially limited by drug-related antigenicity and prohibitively high rates of anaphylaxis with repeat drug administration. In contrast to older generation uricases, pegloticase appears to be less allergenic and has been administered successfully to many patients as repeated intravenous infusions.

### Role in Rheumatic Disease and Indications

Pegloticase is approved for the treatment of hyperuricemia in patients with treatment refractory gout. Approved with an orphan drug status in the United States, pegloticase is indicated in a small subset of patients with gout. Treatment-refractory disease is characterized by severe disabling gout, often accompanied by marked tophaceous deposition and significant comorbidity, in which conventional ULT is either contraindicated or ineffective.[116] Pegloticase administration is associated with rapid and marked declines in sUA. In clinical trials, pegloticase use resulted in plasma concentrations as low as 0.5 to 1 mg/dL within 24 hours of an initial dose.[117] As a consequence, pegloticase administration has been associated with dramatic regression of tophi[118] and depletion of urate stores, raising speculation that pegloticase or other uricase formulations could play a role as an induction therapy in select patients with severe tophaceous gout and excessive total body urate stores (Figure 66-3).

### Chemical Structure and Mechanism of Action

Pegloticase is a recombinant mammalian uricase linked to polyethylene glycol (PEG). Pegloticase facilitates the conversion of UA into allantoin. The conversion of allantoin from UA generates hydrogen peroxide ($H_2O_2$) that is rapidly scavenged by erythrocytes.[119]

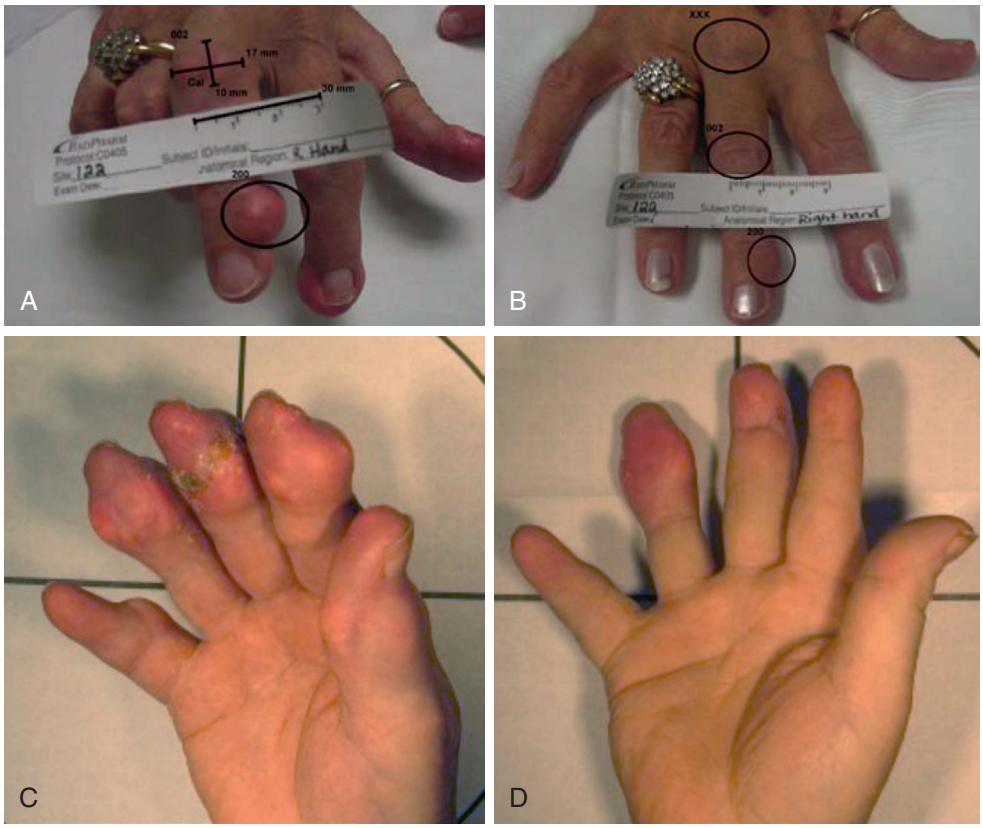

**Figure 66-3** **A**, Baseline tophus in patient 1 involving the medial aspect of the right third distal interphalangeal (DIP) joint. **B**, Same patient with resolution of tophus after 13 weeks of pegloticase therapy. **C**, Baseline tophi in patient 2, and (**D**) same patient after 25 weeks of pegloticase treatment *(From Baraf HS, et al: Tophus burden reduction with pegloticase: results from phase 3 ransomized trials and open-label extension in patients with chronic gout refractory to conventional therapy.* Arthritis Res Ther *15:R137, 2013, with permission.)*

## Pharmacology

The pharmacokinetics of pegloticase follows a one-compartment linear model. Maximum serum concentrations and the magnitude of urate-lowering effect after intravenous pegloticase administration increase in a dose-dependent fashion.[120] Pegloticase pharmacokinetics are not affected by age, sex, weight, or underlying renal function. A single dose of pegloticase (≥2 mg) has been shown to have a highly variable duration of effect, suppressing sUA to less than 7.0 mg/dL for periods ranging from 1 to 8 days.[120] The high degree of variability in drug elimination and treatment durability appears to be related at least in part to the presence and concentration of circulating anti-pegloticase antibody (see Dose and Drug Administration below).

## Dose and Drug Administration

Pegloticase is approved for intravenous infusion administered during a 2-hour period at a dose of 8 mg every 2 weeks (see Table 66-1). Regulatory approval of pegloticase is based on results from two 6-month replicate randomized placebo-controlled studies[117] in addition to open-label follow-up extensions ($n$ = 212). Patients in these clinical trials had pre-treatment sUA exceeding 8.0 mg/dL, had symptomatic gout, and had failed prior allopurinol therapy based on reported intolerance or ineffectiveness at a maximum medically appropriate dose. Patients received prophylaxis against infusion reactions (see Table 66-1) and against rebound gout flares (colchicine, NSAID, or glucocorticoid). The primary outcome for both randomized studies was a sUA of less than 6.0 mg/dL for 80% or more of the sampling period from month 3 to 6 of follow-up. This outcome was met by 47% and 38% of patients who received pegloticase, 8 mg by IV every 2 weeks, in the two randomized studies.[117] In pooled analyses, 40% of patients with baseline tophi who received pegloticase, 8 mg every 2 weeks, (vs. 7% of patients receiving placebo) had complete resolution of tophi by the time of the final study visit.

Although nonresponders generally experienced plasma urate reductions equally as dramatic as responders after their initial pegloticase infusion, nonresponders usually lost the treatment effect within the first 3 months of therapy. Efficacy loss, defined as sUA rising higher than 6.0 mg/dL during treatment, appears to be strongly associated with the formation of antipegloticase antibodies (primarily immunoglobulin (Ig) M and IgG subtypes that bind the PEG portion of the drug). Clinically meaningful manifestations of anti-pegloticase antibody formation, including an increased risk of anaphylaxis and neutralization of drug effect, appear to be most striking at antibody titers exceeding 1:2430. It is recommended that sUA, rather than drug antibody titers, be monitored closely during treatment with discontinuation of pegloticase if preinfusion sUA increases higher than 6.0 mg/dL.[121]

### Toxicity

The most common serious adverse event observed with pegloticase therapy is anaphylaxis, observed in approximately 7% of patients (see Table 66-1). Antipegloticase antibody can be detected in a vast majority of patients (~90%) receiving treatment, although clinically meaningful antibody titers are encountered less often. In clinical studies, anaphylaxis occurred despite prophylaxis that included antihistamine and glucocorticoid therapy with an onset of symptoms typically seen within 2 hours of drug administration. Treatment-related anaphylaxis is far more common among patients with treatment failure; thus close sUA surveillance and discontinuation of pegloticase for patients with sUA higher than 6.0 mg/dL is an essential element in risk mitigation. Post hoc analysis of the replicate studies suggests that nearly all cases of anaphylaxis would have been prevented with the use of this strategy. The concomitant use of other ULT should be avoided, which might otherwise mask antibody-mediated increases in sUA. Recognizing overlap with symptoms of anaphylaxis, infusion reactions occur in as many as 25% of patients receiving pegloticase with manifestations that include urticaria, dyspnea, chest discomfort, pain, or both, erythema, and pruritis. Infusion reactions can occur anytime in the course of therapy, with rare reports of delayed hypersensitivity reactions.

As with other ULTs, rebound gout flare is common after the administration of pegloticase. Other adverse events observed with pegloticase are summarized in Table 66-1. In the clinical studies and in open-label follow-up, exacerbations of congestive heart failure were also more common with pegloticase than placebo although a causal association with active drug therapy has not been established.[121]

### Fertility, Pregnancy, and Lactation

No studies have examined the impact of pegloticase on either fertility or pregnancy in humans, and it is unknown whether pegloticase is excreted in human milk. In the absence of appropriate human studies, pegloticase is classified as Pregnancy Category C and it is not recommended for use in nursing mothers.

### Drug Interactions and Contraindications

Recognizing that antipegloticase antibodies bind the PEG portion of the agent, pegloticase should be used with caution in patients receiving other PEG-containing therapies. Whether the formation of antipegloticase antibodies precludes or impacts future treatment with other PEGylated molecules is unknown. Pegloticase is contraindicated in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency because of an increased risk of hemolysis and methemoglobinemia. Patients with an increased risk should be screened for G6PD deficiency before initiation.[121]

## URATE-LOWERING DRUGS IN DEVELOPMENT

The treatment armamentarium in chronic gout will likely grow in the future, with several novel ULTs under development, including novel uricosurics and agents that inhibit endogenous UA synthesis.[122]

Ulodesine (BCX4208) represents a potentially novel mechanism by inhibiting endogenous UA synthesis via the inhibition of purine nucleoside phosphorylase (PNP). Along with adenosine deaminase, PNP plays a role in purine degradation, acting proximally to XO by metabolizing inosine into hypoxanthine. In a 3-week study of 60 patients with gout (all with baseline sUA >8.0 mg/dL), 31% to 36% of patients given ulodesine (40 mg, 80 mg, and 120 mg daily) achieved a final sUA of less than 6.0 mg/dL.[123] Decreases in sUA ranged from 2.7 to 3.4 mg/dL compared with a decline of just 0.4 mg/dL with placebo. Well tolerated in this short-term study, the potential immunosuppressive effects of ulodesine warrant further study, recognizing that inherited PNP deficiency results in severe combined immunodeficiency.

Lesinurad (RDEA594) is a metabolite of RDEA806, a non-nucleoside reverse transcriptase inhibitor, and was approved for use in gout by the U.S. Food and Drug Administration (FDA) in December, 2015. Lesinurad appears to specifically inhibit URAT1 and OAT4, lacking a significant effects on other organic anion transporters (see Figure 66-2).[124] More selective inhibition may limit drug interactions that complicate probenecid use. In contrast to probenecid,[65] the co-administration of lesinurad does not appear to increase the renal elimination of oxypurinol or febuxostat,[125] suggesting that this may be an ideal uricosuric to use in combination with first-line XO inhibitors. The addition of lesinurad to allopurinol (300 mg/day) led to dose-dependent declines in sUA.[126] After the addition of lesinurad (400 or 600 mg/day), the proportion of patients achieving sUA goal of less than 6.0 mg/dL with febuxostat alone (40 or 80 mg/day) increased from between 56% and 67% to 100%.[127]

In addition to displaying urate-lowering properties, tranilast has been studied for possible therapeutic effects in a number of conditions, including allergy, malignancy, and conditions characterized by excessive tissue fibrosis. Similar to currently available uricosurics, the urate-lowering effects of tranilast are mediated through the inhibition of URAT1 and GLUT9 transporters (see Figure 66-2).[128] In a preliminary study, tranilast administration (300 mg/day) was associated with a 14% decline in sUA with 28% of patients achieving a sUA less than 6.0 mg/dL.[129]

A peroxisome-proliferator–activated gamma modulator, arhalofenate (MBX-102) has been highlighted in recent studies as a novel agent demonstrating dual uricosuric and anti-inflammatory effects.[122] In addition to inhibiting renal UA transporters (URAT1, OAT4, OAT10), in vitro studies have shown that the agent effectively blocks monosodium urate–induced production of IL-1. Large-scale human studies of arhalofenate in the treatment of gout have yet to be undertaken.

Levotofisopam is a benzodiazepine derivative approved in countries outside the United States for the treatment of anxiety and autonomic instability and has recently been demonstrated to yield potentially important urate-lowering effects. In an initial proof-of-concept study involving 13 patients with gout, patients were given levotofisopam 50 mg twice daily, with a mean sUA reduction of 49% after 1 week of treatment.[122] The treatment was well tolerated, and all patients achieved a sUA of less than 6.0 mg/dL.

CHAPTER 67

# Analgesic Agents in Rheumatic Disease

Gregory R. Polston • Mark S. Wallace

**KEY POINTS**

- Numerous analgesic agents can be used to treat pain related to rheumatic disease.
- Acetaminophen, nonsteroidal anti-inflammatory agents, and opioids have intrinsic analgesic properties that are most efficacious for nociceptive and inflammatory pain.
- Anti-depressants, anti-convulsants, and muscle relaxants lack intrinsic analgesic properties but are effective in neuropathic and functional pain and can enhance the effects of other analgesics.
- The use of opioids for chronic pain remains controversial, but with proper patient selection and adherence to universal precautions, risks can be minimized and benefits maximized.
- Many drugs can increase and decrease the metabolism of opioids through interaction of CYP2DG and CYP3A4 systems. This can greatly vary the effects of opioid in different individuals.
- Increased reports of methadone overdose are thought to be the result of coadministration of drugs that inhibit the CYP3A4 system.
- Although the tricyclic anti-depressants are efficacious in a variety of pain syndromes, compliance is an issue because of unacceptable side effects and delayed onset.
- Newer serotonin and norepinephrine reuptake inhibitors (such as duloxetine) are better tolerated and have a faster onset than older tricyclic anti-depressants. Numerous anti-convulsants have been studied with conflicting results. Only gabapentin and pregabalin consistently demonstrate efficacy Muscle relaxants are intended for short-term use only.

Pain is the most common reason for patients to seek medical attention, yet undertreatment of acute and chronic pain persists despite decades of efforts to provide clinicians with information about analgesics.[1] A major consequence of physicians undertreating patients who initially are seen with pain as a result of rheumatic disease is the development of chronic pain. Chronic pain has been demonstrated to have deleterious effects on many aspects of a patient's daily life. These effects include deterioration in physical functioning, the development of psychologic distress and psychiatric disorders, and impairments in interpersonal functioning.[2] In addition to personal suffering, chronic pain imposes a burden on society in increased health care costs, disability, and lost workdays.

## THE PHYSIOLOGY OF PAIN PERCEPTION (THE PAIN EXPERIENCE)

The "pain experience" involves more than just the sensation of pain. Pain activates many areas of the brain that interact, resulting in the pain experience, which will differ among individual patients. The "pain experience" involves more than just the sensation of pain. Pain activates many areas of the brain that interact and result in the pain experience, which will differ among individual patients. The pain experience involves three components: biologic, psychological, and sociological. As described in this chapter, activation of various parts of the nervous system will contribute to each of these components. The three components of the pain experience include (1) sensory/discriminative (biologic), (2) affective/emotional (psychological), and (3) evaluative/cognitive (sociological).[3]

The sensory/discriminative component of pain provides information on the intensity, location, and quality of the pain. These pathways consist of peripheral receptor activation, axon depolarization, and ascending pathways to the cortex for processing.

The ascending pathways that carry impulses from the nociceptor to the sensory cortex also give off fibers to brain stem structures and deep brain structures. Activation of these structures in the brain stem and deep brain will stimulate emotional and sympathetic responses from the individual, leading to the emotional/affective component of pain.

Finally, ascending pain pathways also send projections to the forebrain structures, where the pain is processed on a cognitive and evaluative level. This process explains why patients respond differently to pain on the basis of culture, gender, and past experiences.

The main neurotransmitter in primary afferents is the excitatory amino acid glutamate. Activation of nociceptors causes the release of glutamate from pre-synaptic terminals in the spinal cord dorsal horn. This release acts on the ionotropic glutamate receptor amino-3-hydroxy-5-methylisoxazole-4-proprionic acid postsynaptically to cause rapid depolarization of dorsal horn neurons and, if threshold is reached, action potential discharge.[4]

## PAIN CLASSIFICATION

Pain can be mechanistically divided into types: nociceptive, inflammatory, functional, and neuropathic. Nociceptive pain is transient pain in response to a noxious stimulus that activates high threshold afferents. Nociceptive pain serves a protective function. Inflammatory pain is the spontaneous

hypersensitivity to pain that occurs in response to tissue damage and inflammation (e.g., post-operative pain, traumatic pain, arthritis pain). Functional pain is hypersensitivity to pain resulting from abnormal central processing of normal input (e.g., pathologic irritable bowel syndrome, fibromyalgia). Neuropathic pain is spontaneous pain and hypersensitivity to pain that occurs in association with damage to or lesions of the nervous system (e.g., peripheral neuropathy, postherpetic neuralgia). Nociceptive pain and inflammatory pain are prevalent in rheumatic disease. Functional pain and neuropathic pain are probably less prevalent in rheumatic disease; however, both should always be considered because poorly controlled pain can lead to nervous system dysfunction and functional and neuropathic pain.[5]

## PHARMACOLOGIC TREATMENT OF CHRONIC PAIN

The efficacy of analgesics is dependent on the pain mechanism. Primary analgesics are more efficacious in nociceptive and inflammatory pain, whereas adjuvant agents are more efficacious in neuropathic and functional pain. Each pain classification involves different pain mechanisms, and within each classification are multiple different pain mechanisms.[6]

Pain is mediated through both peripheral and central mechanisms, and often more than one mechanism of pain is active in a given patient. Thus the use of two or more agents with differing mechanisms increases the likelihood of interrupting pain signals and relieving pain.

Pharmacologic agents for the management of chronic pain are divided into primary analgesics, which have intrinsic analgesic properties, and adjunct analgesics, which may have primary analgesic properties in neuropathic pain but usually enhance the analgesic effects of primary analgesics when used in non-neuropathic pain syndromes. Table 67-1 summarizes these agents. Nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase (COX)-2 inhibitors will be discussed elsewhere (see Chapter 59).

## OPIOIDS

Numerous studies have demonstrated the efficacy of opioids in a variety of chronic pain states, including neuropathic and non-neuropathic. However, studies to document long-term efficacy have not been conducted. Long-term opioid therapy to treat chronic pain remains controversial. During the last century, the pendulum has swung back and forth with regard to the use of the opioids to treat pain. In the mid-20th century, opioids were limited because of fears of addiction and diversion. In the late 20th century, the pendulum swung to the other side, and physicians used opioids liberally to treat chronic pain. With the turn of the 21st century, the pendulum is moving back toward the middle with recognition of the importance of opioids in chronic pain management but an understanding of the need to balance these benefits with risks. Recently published guidelines acknowledge that opioid analgesics have an important role in pain management and that underuse of these agents may contribute to suboptimal pain management.[7] However, these guidelines also acknowledge that abuse of prescription opioids has become an epidemic, with dramatic increases seen in the United States. Therefore a set of universal precautions has been developed as a guide to help physicians who prescribe opioids[8] (Table 67-2).

Evaluating patients with chronic noncancer pain can be problematic because the perception of pain is not only dependent on physiologic factors but also the patient's psychological and social background. Thus developing a pain treatment plan that includes opioids can be challenging. Historically, the use of opioids was reserved for short-term treatment or for end-of-life care. In the late 1980s, however, this practice changed. Chronic pain became recognized as a disease, and experts began recommending more liberal prescription practices. Unfortunately, while the use of opioid prescriptions increased, so too did opioid overdoses and prescription drug substance abuse disorders. The increase in abuse and overdoses has become so rampant that we now are in the midst of an opioid epidemic that presents dangers not only for patients but for society as a whole. To combat this problem, a number of strategies have been proposed to identify patients who are more likely to benefit from opioid therapy, thus improving patient selection and outcome. These include specific guidelines to always consider nonopioid therapies first, as well as guidelines for upper-dose daily limits for opioid analgesics.[9] Additional recommendations include taking a full social history at the

**TABLE 67-1** Analgesic Options to Treat Chronic Pain

| |
|---|
| Primary analgesics |
| Acetaminophen |
| Nonsteroidal anti-inflammatory drugs/cyclooxygenase-2 inhibitors |
| Opioids |
| Adjunct analgesics |
| Tricyclic anti-depressants |
| Serotonin-norepinephrine reuptake inhibitors |
| Anti-convulsants |
| Muscle relaxants |
| Topical agents |

**TABLE 67-2** Universal Precautions for Long-Term Opioid Use

| |
|---|
| Diagnosis with appropriate differential |
| Psychological assessment of patient, including risk of addictive disorders |
| Informed consent |
| Treatment agreement |
| Preintervention and postintervention assessment of pain level and function |
| Appropriate trial of opioid therapy with or without adjunctive medication |
| Reassessment of pain score and level of function |
| Regular assessment of the "4 A's" (analgesia, activities of daily living, adverse effects, and aberrant drug-taking behaviors) |
| Periodic review of pain diagnosis and comorbid conditions, including addictive disease |
| Documentation |

From Gourlay DL, Heit HA, Almahrezi A: Universal precautions in pain medicine: a rational approach to the treatment of chronic pain. *Pain Med* 6:107-112, 2005.

**TABLE 67-3** Risk Factors for Poor Patient Outcomes with Chronic Opioid Therapy

| |
|---|
| **High** |
| Patient intake of >120 mg morphine equivalent/day or methadone |
| High abuse risk (current abuse, young patient age, significant psychiatric history, prior aberrant behaviors, initial screening score) |
| Lack of clear reason for pain |
| Comorbidity (renal, hepatic, respiratory, sleep apnea) |
| Use of other sedatives, stimulants, anxiolytics, or sleeping medication |
| Multiple medications to combat side effects |
| Younger patient age |
| Lack of functional improvement |
| Rapid dose escalation after starting medication |
| Poorly treated mental health issues |
| Others in home with high risk for diversion or unstable living conditions |
| **Moderate** |
| Patient intake of 40 to 120 mg morphine equivalent/day |
| Prior patient substance abuse diagnosis in remission for greater than 6 months |
| Moderate risk on initial risk questionnaire |
| Prescriber "uneasy" about providing opioids for the patient |
| **Low** |
| Patient intake <40 mg morphine equivalent/day |
| Compliant with medication and attempting nonopioid therapies |
| Clear indication for pain |
| Low risk on initial risk questionnaire |
| Clear functional improvement |

start of therapy. This history should include alcohol use, illegal drug use, family history of substance abuse, and whether others in the patient's home are at risk for misuse. Using validated patient questionnaires to predict success with chronic opioid therapy such as the Opioid Risk Tool,[10] Diagnosis, Intractability, Risk, Efficacy (DIRE),[11] or the Screener and Opioid Assessment for Patients with Pain[12] is also recommended. Along with a complete physical examination, the patient can be stratified into risk groups (low, medium, high) (Table 67-3), which will offer insight as to how best to monitor individual patients. Other efforts include making every patient sign an opioid agreement, consent to random drug testing, and demonstrate clear functional improvement to continue this therapy. State prescription and monitoring programs have been created to help document compliance and identify "doctor shopping." State and national regulations, including Risk Evaluation and Mitigation Strategies (REMS)[13] for all long-acting and extended-release opioids have also been implemented. The REMS program requires specific education for providers, patients, and caregivers regarding the use of these drugs, along with documentation of any benefit and review of misuse, abuse, or addiction. Another promising method is the development of new formulations of long-acting opioid analgesics with abuse-deterrent and tamper-resistant formulations.

Along with the recommendations above, the physician should first prescribe a short-acting weak opioid such as hydrocodone or codeine. If the patient requires more than three or four short-acting weak opioids per day, consider converting to a long-acting opioid if the pain is continuous. It is generally believed that controlled-release or long-acting opioids provide convenience to patients by reducing the number of daily doses required and also provide a pharmacokinetic profile that results in reduced serum level peaks and troughs. These characteristics result in an improvement in the consistency of effective analgesia and a potential reduction in opioid-related side effects that are often correlated with high peak serum levels. Physicians should prescribe long-acting opioids only for around-the-clock pain and not for intermittent or breakthrough pain. No clinical evidence exists that long-acting opioids decrease the risk of misuse or addiction, and there is concern that the total daily dose of opioids increases simply because of higher-dose increments. When a patient switches to a long-acting opioid, access to a short-acting opioid for breakthrough pain can be continued but should be monitored and controlled. Evaluation by a pain specialist may be considered when morphine equianalgesic dosages exceed 90 mg/day. The benefits of levels higher than 180 mg/day have not been established, and recent evidence suggests a significant increase in morbidity and mortality when doses exceed 100 mg/day.[14]

## Opiate Receptor Classes

Early work by Martin and associates led to the postulation of three opiate receptors: mu, kappa, and sigma.[15] Later studies by Kosterlitz and colleagues led to the identification of the delta opioid receptor.[16] With the exception of the sigma receptor, all of the opiate receptors are responsible for opioid-induced analgesia. Opioid receptors are mediated through a G protein, leading to a cascade of events that typically inhibit neuron activation.[17] Persistent activation of G protein–coupled receptors typically results in progressive loss of effect, known as *tolerance* (discussed later).

## Opiate Receptor Distribution and Mechanisms of Opioid-Induced Analgesia

The main sites of action of the opiates are believed to be located in the brain and spinal cord; however, under some circumstances, peripheral mechanisms are involved. Responses of an individual patient may vary dramatically with different mu-opioid receptor (MOR) agonists. If problems are encountered with one drug, the prescribing physician should try another. Mechanisms underlying variations in individual responses to morphine-like agonists are poorly understood; however, they are thought to be the result of MOR polymorphisms.

Numerous sites in the brain have MORs. Activation of receptors located in the mesencephalic periaqueductal gray[18] appears to be the most important cause of opioid-induced analgesia. MOR agonists block release of the inhibitory transmitter γ-aminobutyric acid (GABA)[19] from tonically active periaqueductal gray (PAG) systems that regulate activity in projections from the PAG to the medulla. This results in an increase in PAG outflow to the medulla, leading to activation of medullospinal projections and release of noradrenaline or serotonin at the level of the spinal dorsal horn. This release can attenuate dorsal horn excitability and analgesia. PAG activation can also increase the excitability of the dorsal raphe and the locus coeruleus, from which ascending serotonergic and noradrenergic projections originate to project to the limbic forebrain. This

process leads to the euphoric effects sometimes experienced with systemic MOR agonists.[20]

In the spinal cord, MOR agonists are limited for the most part to the substantia gelatinosa of the superficial dorsal horn, the region in which small, high-threshold sensory afferents terminate. Most of these opiate receptors are located pre-synaptically and postsynaptically on small peptidergic primary afferent C fibers. Pre-synaptic activation of the MOR prevents the opening of voltage-sensitive calcium ion channels, thereby preventing transmitter release. Postsynaptic activation of the MOR increases potassium conductance, resulting in hyperpolarization and reduced excitation induced by the pre-synaptic release of glutamate.[21] The ability of spinal opiates to reduce the release of excitatory neurotransmitters from C fibers pre-synaptically and to decrease the excitability of dorsal horn neurons postsynaptically is believed to account for powerful and selective effects upon spinal nociceptive processing. In humans, an extensive literature indicates that a variety of opiates delivered spinally (intrathecally or epidurally) can induce a powerful analgesia.[21]

Systemic delivery of the opioids will reduce nociceptive pain through a central mechanism located in the brain and spinal cord, as described previously, whereas the peripheral application has no effect. However, under conditions of inflammation, which result in an exaggerated pain response (hyperalgesia), the peripheral application of the opioids will reduce the hyperalgesia. This action is believed to be mediated by opiate receptors on the peripheral terminals of small primary afferents that become active under inflammatory conditions. Whether the effects are uniquely on the afferent terminal or on inflammatory cells that release products that sensitize the nerve terminal is not known.[22]

## Tolerance

With time, a given dose of an opioid shows less effect, and an increased dose is required to produce the same physiologic response. Tolerance to different effects of opioids occurs at different rates. For example, tolerance to sedation and nausea occurs earlier than analgesic tolerance. Some effects, such as constipation, never show tolerance.

The mechanism of opioid tolerance is controversial. Apparent opioid tolerance may be an indication of disease progression with a resultant increase in pain intensity; this is the first event that should be ruled out before true tolerance is assumed. Many cellular mechanisms can lead to tolerance. First, long-term opioid exposure can lead to receptor internalization, dephosphorylation, and desensitization. Second, exposure to high doses of opioids can lead to an increase in intra-cellular cyclic adenosine monophosphate (cAMP), activation of bulbospinal pathways, and glutamate receptor phosphorylation, producing an excitatory state (opioid-induced hyperalgesia).[23] An incomplete cross-tolerance occurs between the various opioids, and when a patient develops tolerance to one opioid, switching to another opioid can result in an increased effect.

## Physical Dependence

Physical dependence is not addiction (and the terms should not be used interchangeably). Physical dependence is a pharmacologic effect characteristic of a number of different types of medications. Physical dependence is defined as the occurrence of an abstinence syndrome (withdrawal reaction) following abrupt discontinuation of the drug, substantial dose reduction, or administration of an antagonist. Physical dependence is generally assumed to occur with regular opioid use for as brief a period as a few days.

Opioid withdrawal is manifested by significant somatomotor and autonomic outflow (reflected by agitation, hyperalgesia, hyperthermia, hypertension, diarrhea, pupillary dilation, and release of virtually all pituitary and adrenomedullary hormones) and by affective symptoms (dysphoria, anxiety, and depression).[24] Opioid withdrawal can be minimized by slowly tapering the opioid. These phenomena are considered to be highly aversive and motivate the drug recipient to make robust efforts to avoid the withdrawal state. Initially, drug addicts are driven to repeated doses of opioids because of the euphoric effects. However, with time, the euphoric effects are lessened, and addicts are driven to continue use to avoid withdrawal.

## Addiction

Identification of the disease of addiction is important for safe and effective clinical management of pain in individuals with addictive disorders. The disease of addiction affects approximately 10% of the general population, and its prevalence may be higher in subpopulations of patients with pain. Active addiction is a contraindication to the use of the opioids; a past history is a relative contraindication, but opioids can be used successfully with appropriate monitoring. A persistent misunderstanding is prevalent among health care providers, regulators, and the general population regarding the nature and manifestations of addiction, which may result in undertreatment of pain and stigmatization of patients who use opioids for pain control.

Evaluation for addiction in a patient who is prescribed long-term opioids for pain control is often problematic. This risk of opioid addiction and misuse can be assessed with validated questionnaires (Table 67-4).[10] Although the concept of addiction may include the symptoms of physical dependence and tolerance, physical dependence or tolerance alone does not equate with addiction. In the chronic pain patient who is taking long-term opioids, physical dependence and tolerance should be expected, but the maladaptive behavior changes associated with addiction are not expected.[25]

Addiction is a behavioral pattern characterized by compulsive use of a drug and overwhelming involvement with its procurement and use in spite of potential harm.[24,26] For patients with continuous pain, inadequate pain management (e.g., as-needed dosing schedule, use of drugs with inadequate potency, use of dosing intervals that are too long) can lead to behavioral symptoms that mimic those seen with psychological dependence and can be mistaken for addiction termed *pseudoaddiction*. In the case of pseudoaddiction, problem behaviors resolve after sufficient pain relief is established. However, behaviors related to true addiction may also resolve after dose escalation. Thus it can be difficult to distinguish pseudoaddiction from true addiction; careful evaluation and management may be required until the circumstances are sorted out (see Table 67-4).[27]

## Opioid Pharmacology

### Morphine

Morphine is the gold standard against which all other opioids are measured. Morphine can be administered by oral, rectal, subcutaneous, intravenous, intramuscular, and intraspinal routes. Oral bioavailability of morphine is approximately 25% (range, 10% to 40%). Peak plasma concentrations occur 0.5 to 1 hour after ingestion, with a half-life of approximately 3 to 4 hours. To increase the dosing interval of oral morphine, several sustained- and controlled-release preparations have been developed (Table 67-5). The average protein binding of morphine is approximately 35%, but this decreases with renal and hepatic dysfunction. Because of the hydrophilicity of morphine, poor central nervous system (CNS) penetration occurs and little tissue accumulation with repeated dosing. Morphine is metabolized primarily in the liver to two main metabolites: morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). M3G is the primary metabolite with potent CNS excitatory properties. Because of its polarity, CNS penetration is poor; however, in renal failure, M3G plasma concentrations can be high enough to drive this metabolite into the CNS, leading to excitation. M6G possesses potent MOR agonism, but because of its high polarity, CNS penetration is poor. However, similar to M3G, M6G can accumulate in renal impairment, leading to exaggerated opioid effects. Only approximately 10% of unmetabolized morphine is excreted renally, whereas 90% is excreted renally as morphine glucuronide (70% to 80%) and normorphine (5% to 10%) conjugates.[28]

### Methadone

Methadone is a long-acting MOR agonist with potency similar to that of morphine but with two important differences[19]: (1) It has a long half-life, and (2) it has high oral bioavailability. Routes of administration are oral and intravenous, with oral delivery by far the most common. Intravenous routes have been used as a single loading dose for post-operative pain control. Because of its low hepatic clearance and therefore low first-pass effect, oral bioavailability is approximately 80%. Methadone has higher lipid solubility than morphine, which results in faster CNS penetration and onset of action; however, its lipid solubility leads to a higher volume of distribution and a shorter duration of action with initial dosing. Low hepatic clearance leads to accumulation, a longer duration of action, and possible overdose with repeated dosing.

Because of the long half-life of methadone (average, 15 to 30 hours, with published reports ranging from 8 to 59 hours) with drug accumulation during several days, methadone needs to be administered with caution with long intervals between dose adjustments (5 to 7 days). Deaths have been reported with the use of methadone for chronic pain, and in November 2006, the U.S. Food and Drug Administration (FDA) issued a public health advisory for methadone with a black box warning. Although details are often unclear, many of these deaths may be the result of conversion of patients from other opioids to methadone. Methadone has been associated with QRS prolongation, which can lead to sudden cardiac death. If a physician is unfamiliar with the use of methadone, he or she should seek consultation with a pain specialist, especially when considering prescribing methadone at greater than a low dose (20 to 30 mg/day).[29]

The L-isomer of methadone possesses opioid activity, whereas the D-isomer is weak or inactive as an opioid. Evidence suggests that D-methadone is anti-nociceptive as a result of its *N*-methyl-D-aspartate (NMDA) receptor antagonist activity, making methadone attractive in treating neuropathic pain.[30]

Methadone is metabolized primarily by CYP3A4, secondarily by CYP2D6, and, to a smaller extent, by CYP1A2 and additional enzymes that are under study. CYP3A4, the most abundant metabolic enzyme in the body, can vary

30-fold among individuals in terms of its presence and activity in the liver. In addition, drugs that inhibit this enzyme (several anti-retrovirals, clarithromycin, itraconazole, ketoconazole, nefazodone, telithromycin, aprepitant, diltiazem, erythromycin, fluconazole, grapefruit juice, verapamil, cimetidine, and others) will increase the effect of methadone, possibly leading to overdose. This enzyme is also found in the gastrointestinal tract, so methadone metabolism actually starts before the drug enters the circulatory system. The amount of this enzyme in the intestine can vary as much as 11-fold, partially accounting for the variable breakdown of methadone.[31]

Because the half-life of methadone is so long, it has been used extensively to treat opioid dependence and withdrawal. The use of methadone to treat addiction requires a separate clinic and physician license. However, methadone can be used to treat pain under the routine medical Drug Enforcement Administration[32] license.

### Fentanyl

Fentanyl is a potent opioid with very high lipid solubility. This high lipid solubility leads to fast onset, a short duration of action, high protein binding (80%), and a high volume of distribution. The high volume of distribution accounts for the short duration of action because of the high concentration gradient from the plasma to fat and muscle. However, with repeated dosing, the duration of action increases while fat and muscle stores become saturated with fentanyl. Although the analgesic half-life is approximately 1 to 2 hours, the terminal half-life is approximately 3 to 4 hours.[33]

Routes of delivery of fentanyl include transdermal, transmucosal, intravenous, and intraspinal. Subcutaneous delivery is also used in terminal cancer patients. High potency and lipid solubility make fentanyl ideal for transdermal and transmucosal delivery. Two transdermal fentanyl patches are available on the market: reservoir and matrix. The reservoir patch can be accessed and the fentanyl extracted, whereas the matrix patch is tamperproof. Each system delivers fentanyl during a period of 72 hours; however, some patients will deplete the patch within 48 hours, requiring more frequent patch changes. This variability can result from skin perspiration, fat stores, skin temperature, and muscle bulk. After application, the skin serves as a depot, and systemic levels rise for the next 12 to 24 hours, then remain stable until 72 hours. Peak concentration occurs somewhere between 27 and 36 hours (25 microgram patch, 27 hours; 100 microgram patch, 36 hours). A steady state is reached after several applications. After removal of the system, plasma concentrations fall by 50% during 17 hours.[34]

Three transmucosal products are currently available. The fentanyl oralet contains fentanyl in a base of food starch, confectioners' sugar (2 g vs. the 30 g in a Snickers bar), edible glue, citric acid, and artificial berry flavor. The oralet is placed between the patient's gum and cheek and is allowed to dissolve during a period of 15 minutes, with bioavailability of approximately 50%. Onset is fast, with a peak effect at approximately 35 minutes. The fentanyl buccal tablets use an oravescent delivery system that generates a reaction that releases carbon dioxide when the tablet comes in contact with saliva. Transient pH changes accompanying the reaction optimize the dissolution (at a lower pH) of fentanyl through the buccal mucosa. Onset is fast, with a peak effect at approximately 25 minutes. The BioErodible MucoAdhesive (BEMA; BioDelivery Sciences International, Raleigh, N.C.) fentanyl delivery system is composed of water-soluble polymeric films. This system consists of a bioadhesive layer bonded onto an inactive layer. The active ingredient, fentanyl citrate, is incorporated into the bioadhesive layer, which adheres to the moist buccal mucosa. The amount of fentanyl delivered transmucosally is proportional to the film surface area. It is believed that the inactive layer isolates the bioadhesive layer from the saliva, which may optimize delivery of fentanyl across the buccal mucosa, resulting in higher bioavailability (71%). Onset is fast, with a slightly longer peak effect (60 minutes) compared with the other transmucosal systems; however, there may be a longer duration. Chewing and swallowing any transmucosal fentanyl product results in lower bioavailability and peak effect because swallowed fentanyl is poorly absorbed from the gastrointestinal tract.[35]

Fentanyl is metabolized primarily by CYP3A4 to the inactive metabolite norfentanyl; therefore drugs that inhibit this enzyme will increase the drug effect (see prior discussion of methadone). Only opioid-tolerant patients (patients taking >60 mg/day of oral morphine equivalent) should be started on fentanyl products because of risks of severe respiratory depression.

### Oxycodone and Oxymorphone

Oxycodone is administered by the oral or rectal route. Oral bioavailability is 60% and protein binding, 45%. Onset and duration of action are similar to morphine. Oxycodone is metabolized by the CYP3A4 enzyme primarily to noroxycodone, which has approximately 25% potency of the parent compound but also has neuroexcitatory effects. Minor metabolites include oxymorphone, which is more potent than oxycodone and has a longer half-life, and noroxymorphone, which has no analgesic properties.[36]

Oxycodone is available as an immediate-release tablet or solution and as a controlled-release preparation. The controlled-release preparation has an immediate release effect of as much as 40% of the contents, followed by a sustained 12-hour release component. The immediate release effect results in rapid onset, followed by a sustained effect. This can be a disadvantage because the patient may perceive the duration as short when coming down from the high peak plasma concentration caused by the immediate release.

Oxymorphone is a metabolite of oxycodone and can be delivered via the oral and rectal routes. Both the bioavailability and protein binding are low (10%), but the terminal half-life is long (10 to 12 hours). Most of the oxymorphone is metabolized to oxymorphone-3-glucuronide, which is an inactive metabolite. Oxymorphone is available in immediate-release and sustained-release preparations.[37]

### Hydromorphone

Hydromorphone is administered by the oral, intravenous, intramuscular, and subcutaneous routes. Oral bioavailability

is low (ranging from 25% to 50%), and protein binding is less than 20%. The kinetics are very similar to morphine. Hydromorphone has an extensive first-pass effect, and 95% is metabolized to the inactive hydromorphone-3-glucuronide. A 24-hour-release preparation of hydromorphone has been approved by the FDA. This preparation uses an osmotic piston-driven system in pill form that slowly delivers hydromorphone during 24 hours.[38]

### Meperidine

Meperidine can be delivered by the oral, rectal, intravenous, intramuscular, subcutaneous, and intraspinal routes. Meperidine use has decreased with time because of side effects and risks associated with the parent compound and metabolites (see later). Oral bioavailability is approximately 50%, protein binding is approximately 60%, and peak concentrations in plasma usually are observed in 1 to 2 hours. Onset and duration are similar to morphine. Large doses of meperidine repeated at short intervals may produce an excitatory syndrome that includes hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are caused by accumulation of the metabolite, normeperidine, which has a half-life of 15 to 20 hours compared with 3 hours for meperidine. Because normeperidine is eliminated by the kidney and the liver, decreased renal or hepatic function increases the likelihood of such toxicity. As a result of these properties, meperidine is not recommended for the treatment of chronic pain because of concerns over metabolite toxicity. It should not be used for longer than 48 hours or in doses greater than 600 mg/day.[39]

Severe reactions may follow the administration of meperidine to patients being treated with monoamine oxidase (MAO)[40] inhibitors. Two basic types of interactions can be observed. The most prominent is an excitatory reaction ("serotonin syndrome"). This reaction may be the result of the ability of meperidine to block neuronal reuptake of serotonin and resulting serotonergic overactivity. Another type of interaction, a potentiation of opioid effect caused by inhibition of hepatic CYPs, also can be observed in patients taking MAO inhibitors, necessitating a reduction in the doses of opioids.

### Hydrocodone

Hydrocodone is a weak MOR agonist. It is delivered only by the oral route and is mostly prescribed in acetaminophen-containing compounds. It has just been reclassified as a Schedule II opioid because of high abuse rates, numerous overdoses, and unintentional acetaminophen toxicity in the United States. A long-acting hydrocodone that does not contain acetaminophen was approved by the FDA in 2013. Its approval was controversial, and how it should be used in clinical practice is not known. Hydrocodone has an oral bioavailability of approximately 25%, with low protein binding in the rapid-release form. It is metabolized to hydromorphone, but its analgesic activity is not dependent upon metabolism to hydromorphone. However, rapid metabolizers may experience a faster onset of action because of the production of hydromorphone. Onset and duration of effect are similar to morphine.

### Codeine

Codeine has an exceptionally low affinity for the MOR, and the analgesic effect of codeine is caused by its conversion to morphine. The oral bioavailability is approximately 60% and is poorly protein bound. The onset and duration of effect are similar to morphine. It is administered via the oral route.

The conversion of codeine to morphine is effected by CYP2D6. Well-characterized genetic polymorphisms in CYP2D6 lead to the inability to convert codeine to morphine, thus making codeine ineffective as an analgesic for approximately 10% of the white population. Other polymorphisms can lead to enhanced metabolism and thus to increased sensitivity to the effects of codeine.[41] Variation in metabolic efficiency is evident among ethnic groups. For example, Chinese individuals produce less morphine from codeine than whites and are less sensitive to the effects of morphine.[42]

### Tramadol

Tramadol is a synthetic codeine analogue with a dual mechanism of action. Analgesia results through weak MOR agonism and inhibition of uptake of norepinephrine and serotonin.

Tramadol is 68% bioavailable after a single oral dose, with approximately 20% protein binding. Its affinity for the opioid receptor is only equal to that of morphine. However, the primary *O*-demethylated metabolite of tramadol is two to four times as potent as the parent drug and may account for part of the analgesic effect. Tramadol is supplied as a racemic mixture, which is more effective than either enantiomer alone. The (+)-enantiomer binds to the receptor and inhibits serotonin uptake. The (−)-enantiomer inhibits norepinephrine uptake and stimulates $\alpha_2$-adrenergic receptors.[43] The compound undergoes hepatic metabolism and renal excretion, with an elimination half-life of 6 hours for tramadol and 7.5 hours for its active metabolite. Analgesia begins within an hour of oral dosing and peaks within 2 to 3 hours. The duration of analgesia is approximately 6 hours. The maximum recommended daily dose is 400 mg. Tramadol is also available in a 24-hour extended-release preparation.

Physical dependence on and abuse of tramadol have been reported. Although its abuse potential is unclear, tramadol probably should be avoided in patients with a history of addiction. Because of its inhibitory effect on serotonin uptake, tramadol should not be used in patients taking MAO inhibitors and triptans. Seizures have been reported with concomitant use of selective serotonin receptor inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), tricyclic anti-depressants (TCAs), and neuroleptics.[43]

### Tapentadol

Tapentadol is a strong opioid with a dual mechanism of action, similar to tramadol. It is a strong MOR agonist and a serotonin and norepinephrine reuptake inhibitor. Because of its first-pass metabolism, its bioavailability is low (32%) and protein binding is low (20%). The metabolites

of tapentadol are inactive. The half-life is approximately 4 hours.

Similar to tramadol, tapentadol is contraindicated in patients taking MAO inhibitors, triptans, SSRIs, SNRIs, TCAs, and neuroleptics because of the risk of serotonin syndrome. There does not appear to be a risk of seizures, as is seen with tramadol. Tapentadol is currently available as an oral immediate-release drug; however, an extended-release preparation is in development (Figure 67-1).

## Toxicity

### Respiration

Although effects of opioids on respiration are readily demonstrated, clinically significant respiratory depression rarely occurs with standard analgesic doses in the absence of other contributing comorbidities or concomitant use of sedatives. In addition, the respiratory depressant effect of the opioid is significantly reduced with continued opioid use because of patient tolerance. It should be stressed, however, that respiratory depression represents the primary cause of morbidity secondary to opiate therapy.[44] In humans, death from opiate poisoning is nearly always the result of respiratory arrest or obstruction.[45] For example, in November 2006, the FDA notified health care professionals of reports of death and life-threatening adverse events, such as respiratory depression and cardiac arrhythmias, in patients receiving methadone.[46] Methadone appears to be involved in approximately one-third of all prescription opioid–related deaths, exceeding hydrocodone and oxycodone despite being prescribed one-tenth as often. This has led to revisions in methadone conversion tables.

At therapeutic doses, opiates depress all phases of respiration (rate, minute volume, and tidal exchange). High doses can produce irregular and agonal breathing.[47] A number of factors can increase the risk of opioid-induced respiratory depression, even at therapeutic doses. These include[19] (1) concomitant use of sedatives such as alcohol, benzodiazepines, and tranquilizers; (2) obstructive and central sleep apnea; (3) extremes in age (both newborns and elderly); (4) comorbidities such as pulmonary disease and renal disease; and[19] (5) removal of the painful stimulus. Pain serves as a respiratory stimulant, and removal of pain (e.g., neurolytic block with severe cancer pain) will reduce the ventilatory drive, leading to respiratory depression. Dose dumping is the unintentional rapid release of the opioid from controlled-release medications. This can occur after ingestion of alcohol and is thought be one of the causes of overdoses.

### Sedation

Opiates can produce drowsiness and cognitive impairment, which can increase respiratory depression. These effects most typically are noted following initiation of opiate therapy or after a dose increase but usually resolve with continued opioid use. If the sedation does not resolve, other causes of the sedation should be investigated, such as concomitant use of other sedatives or the presence of sleep apnea. In the absence of these variables, opioid rotation may result in less sedation.[48]

### Neuroendocrine Effect

Regulation of the release of hormones and factors from the pituitary is under complex regulation by opiate receptors in the hypothalamic-pituitary-adrenal (HPA) axis. The opioids block the release of a large number of many HPA hormones, including sex hormones, prolactin, oxytocin, growth hormone, and anti-diuretic hormone.

In males, the opioids inhibit adrenal function, resulting in reduced cortisol production and reduced adrenal androgens. In females, the opioids lower luteinizing hormone (LH) and follicle-stimulating hormone (FSH) release. In both males and females, long-term opioid therapy can result in endocrinopathies, including hypogonadotropic hypogonadism, leading to decreased libido, and females may experience menstrual cycle irregularities. These changes are reversible with removal of the opiate. Mechanisms of neuroendocrine effects of the opioids are thought to be the result of a direct effect on the pituitary and an indirect action on the hypothalamus, blocking the release of gonadotropin-releasing hormone (GnRH) and corticotropin-releasing hormone (CRH). Secretion of thyrotropin is relatively unaffected.

Opioids inhibit the release of dopamine from neurons of the tuberoinfundibulum of the arcuate nucleus. Prolactin release from lactotrope cells in the anterior pituitary is under inhibitory control by dopamine; therefore the reduced dopamine caused by the opioids results in an increase in plasma prolactin. Prolactin counteracts the effects of dopamine, which is responsible for sexual arousal, and high levels of prolactin can result in impotence and loss of libido. Long-term opioid use can increase growth hormone by inhibiting somatostatin release; this regulates GH-releasing hormone secretion.[47]

Anti-diuretic hormone (ADH) and oxytocin are synthesized in the perikarya of the magnocellular neurons in the paraventricular and supraoptic nuclei of the hypothalamus and are released from the posterior pituitary. Kappa opioid receptor agonists inhibit the release of oxytocin and anti-diuretic hormone (and cause prominent diuresis). MOR agonists have minimal effect or tend to produce anti-diuretic effects in humans, and reduce oxytocin secretion.[49] Some of the opioids (i.e., morphine) stimulate histamine release, resulting in hypotension and secondary ADH release. The effects of the opioids on vasopressin and oxytocin release may reflect both a direct effect upon terminal secretion and indirect effects upon dopaminergic and noradrenergic modulatory projections into the paraventricular and supraoptic hypothalamus.[50]

### Miosis

Lumination of the pupil activates a reflex arc, which, through local circuitry in the Edinger-Westphal nucleus, activates parasympathetic outflow through the ciliary ganglion to the pupil, producing constriction. The parasympathetic outflow is locally regulated by GABAergic interneurons, and the opiates are believed to block GABAergic interneuron–mediated inhibition, resulting in miosis.[51] At high doses of agonists, the miosis is marked, and pinpoint pupils suggest opioid intoxication. Although some tolerance to the miotic effect develops with therapeutic

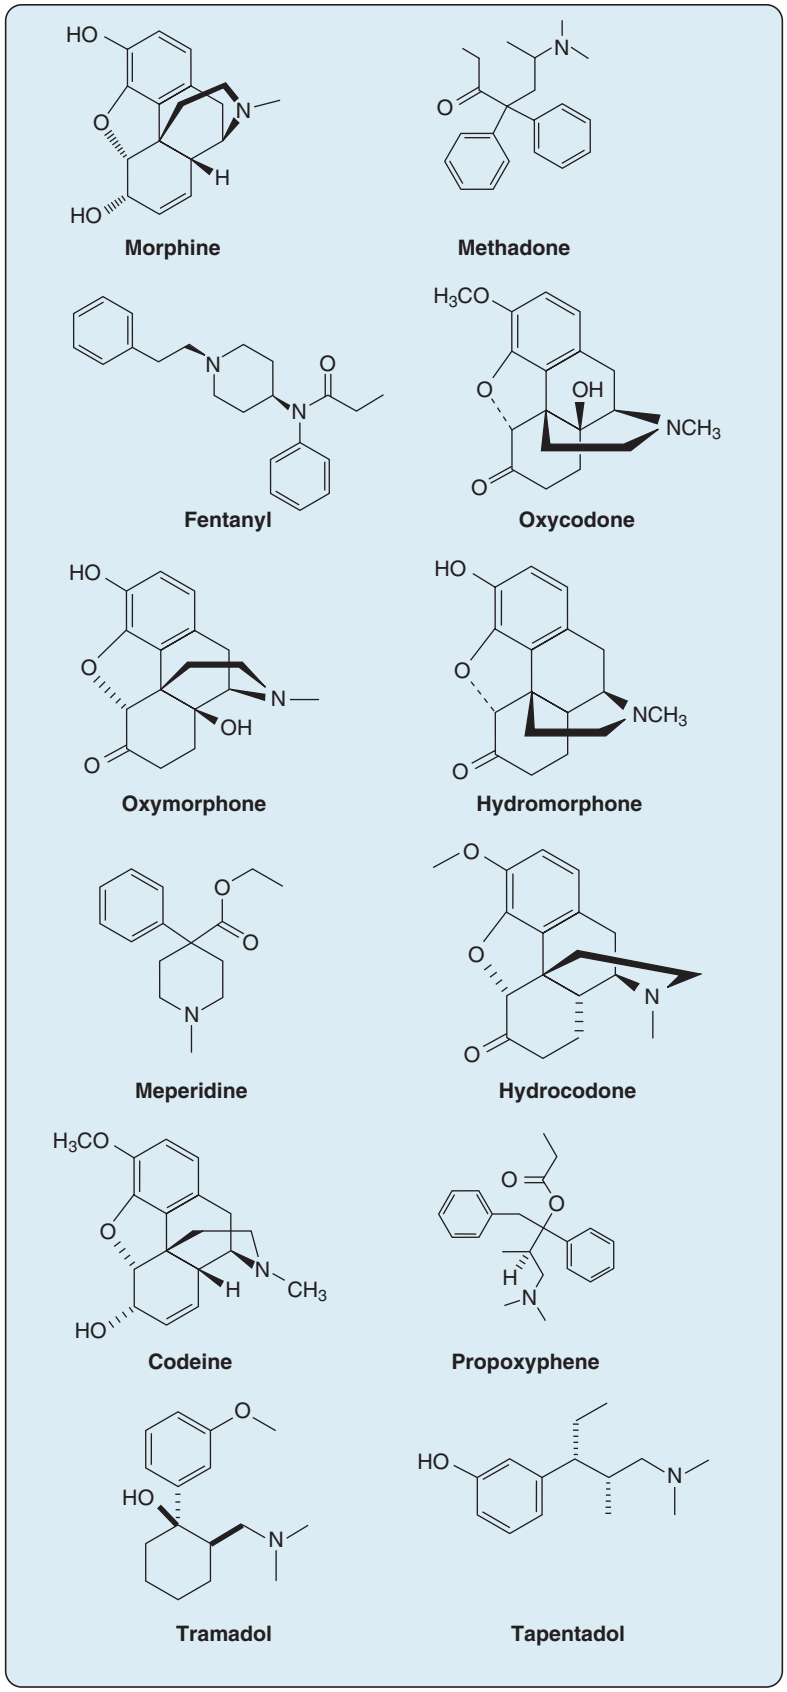

**Figure 67-1** Opioid structures.

doses of the opioids, high circulating concentrations of opioids continue to result in constricted pupils.

### Myoclonus and Seizure

Myoclonus and seizures have been reported in patients receiving high doses of opiates.[49] In addition, seizure-like activity can occur with extremely high doses of the opioids. Seizures may also occur at lower doses of meperidine because of the normeperidine metabolite, which lowers the seizure threshold. Myoclonus and seizure activity is thought to be to the result of inhibition of GABA from inhibitory interneurons in the hippocampal pyramidal cells and dorsal horn cells.[52] The opiates also have a direct stimulatory effect through interaction with G inhibitory and stimulatory-coupled receptors.[53] It has been suggested that, in addition to the normeperidine metabolite, which is seizurogenic, morphine-3-glucuronide (from morphine) may induce myoclonus and seizures at high doses.[54]

### Nausea and Vomiting

The gastrointestinal tract is under the control of the vomiting center located in the brain stem. The vomiting center is activated by the chemoreceptor trigger zone (CRTZ), the vestibular system, and the gastrointestinal tract. The opioids activate the CRTZ, sensitize the vestibular system, and reduce gastric emptying time, all of which will lead to activation of the vomiting center.[55] Drugs that reduce CRTZ activity (antidopaminergics, 5-hydroxytryptamine$_3$ [5-HT$_3$] serotonin receptor antagonists) and vestibular sensitization (anticholinergics, antihistamines) will reduce opioid-induced nausea. Drugs that enhance gastrointestinal motility are also effective (e.g., metoclopramide).[56]

### Constipation

It is estimated that 40% to 95% of patients treated with opioids experience constipation, and that changes in bowel function can be demonstrated even with acute dosing.[57] Opioid receptors are densely distributed in enteric neurons between the myenteric and submucosal plexuses and on a variety of secretory cells.[58] Stimulation of MOR in the intestines reduces propulsatile contractions and diminishes intestinal secretions.[58] The prolonged transit time of the intestinal contents, along with reduced intestinal secretion, leads to increased water absorption, increasing the viscosity of bowel contents and constipation. In addition, anal sphincter tone is increased, and reflex relaxation in response to rectal distension is reduced. All of these effects combine to contribute to morphine-induced constipation.[59] Tolerance to opioid-induced constipation does not occur.

### Biliary Spasm

Relaxation of the sphincter of Oddi is suppressed by the opioids, which can result in an increase in the common bile duct pressure, leading to symptoms of biliary colic. Therefore treatment of the pain of biliary colic with the opioids can lead to an exacerbation of the pain rather than relief.

### Urinary Retention

MOR agonists inhibit the urinary voiding reflex, increase the tone of the external sphincter, and induce bladder relaxation, which can result in urinary retention. This effect is mediated by MOR and delta-opioid receptor activation in the brain and spinal cord. This will result in higher bladder volumes and sometimes requires catheterization.[60]

### Pruritus

Pruritus can occur with all of the MOR agonists. The mechanism is thought to be the result of disinhibition of itch-specific neurons, which have been identified in the spinal dorsal horn.[61] It can occur with both systemic and spinally administered doses but is more common with spinally administered doses.[62] It tends to be focused in the trunk and face.

### Immunosuppression

The effect of the opioids on immune function is controversial. The opioids suppress immune function through a direct effect on immune system cells and indirectly by activating sympathetic outflow and modulation of the HPA axis.[63] A proposed mechanism for the immune suppressive effects of morphine on neutrophils is through nitric oxide–dependent inhibition of nuclear factor-κB (NF-κB) activation.[63] Others have proposed that the induction and activation of mitogen-activated protein (MAP) kinase may play a role.[65] Pain itself is immunosuppressive; therefore a reduction in pain will counteract and probably outweigh the direct immunosuppressive effects of the opioids. In addition, it appears that acute delivery of the opioids is more immunosuppressive than long-term delivery, suggesting tolerance to this effect.

### Sweating

The opioids exert a wide range of effects on thermoregulation, with high doses leading to hyperthermia and low doses leading to hypothermia.[66] Excessive sweating has been reported in as many as 45% of patients taking methadone. The mechanism appears to be related to release of histamine.[67]

## ANTI-DEPRESSANTS

Anti-depressants have long been used to treat chronic pain. In the past, they were more often chosen to improve mood than to treat pain because of coexisting anxiety and depression. After separate studies showed improved pain control in patients without depression, as well as in patients with depression without improvement in mood, it was realized that these medications have independent analgesic actions.[68] Further, improvement in pain is seen earlier and at lower doses than improvements in depression, also demonstrating this analgesic efficacy.[69] A recent meta-analysis of 18 randomized, placebo-controlled studies with multiple anti-depressants concluded that strong evidence exists for the efficacy of anti-depressants for pain relief, fatigue, and sleep disturbance, and in improving health-related quality of life.[70] The FDA has now approved the SNRI duloxetine for

fibromyalgia, diabetic peripheral neuropathy, and chronic musculoskeletal pain, and the SNRI milnacipran for fibromyalgia. Nevertheless, not all anti-depressants are effective pain medications. For example, SSRIs have minimal analgesic properties and therefore have a limited role in the treatment of chronic pain.[71] Trazadone, used mainly for sleep, is another anti-depressant without analgesic actions.

The main site of analgesic action for all of the anti-depressants is thought to be the reuptake inhibition of norepinephrine and serotonin at the level of the spinal cord and higher. This inhibition increases the extra-cellular concentration of these two monoamines, resulting in activation of descending inhibitory pain pathways, and ultimately decreases pain.[72] A peripheral action has also been proposed for the TCAs because topical application produces analgesia in animal models of pain.[72] Current investigation has shown that topical application can result in the inhibition of NMDA receptors and the blockade of sodium and calcium channels, which alone or in combination could explain their peripheral analgesic properties.[72-74] Because TCAs are effective in blocking sodium channels, and the proliferation of sodium channels plays a key role in the pathogenesis of neuropathic pain, this may be one of the main sites of action for these drugs.[75] Finally, TCAs potentiate endogenous opioids (Figure 67-2).[76]

## Tricyclic Anti-depressants

TCAs are considered first-line agents in the treatment of chronic neuropathic pain and fibromyalgia.[77] Two systematic reviews of 17 randomized controlled trials (RCTs) of 10 anti-depressants have shown numbers needed to treat

(NNTs) of approximately 2.5 for neuropathic pain (Table 67-6).[78] All TCAs have shown fairly equal efficacy within the class.

TCAs are usually divided into tertiary amines (amitriptyline, imipramine, and doxepin) and secondary amines (nortriptyline and desipramine). Nortriptyline and desipramine are demethylated in the liver from amitriptyline and imipramine, respectively. The tertiary amines tend to block the reuptake of serotonin more than norepinephrine, and the secondary amines are more selective in their inhibition of norepinephrine uptake.

Tricyclics should be started at the lowest dose possible and titrated slowly. A typical starting dose for amitriptyline, nortriptyline, or desipramine is as low as 5 to 10 mg before bedtime. Doses can be increased by the same amount as the starting dose approximately every 7 days (Table 67-7). Studies have shown improved analgesia with amitriptyline in the range of 25 to 50 mg, but some studies have gone as high as 200 mg. Response should be seen within 3 to 4 weeks (see Table 67-7).

### Side Effects

Unfortunately, side effects with all of the TCAs are common and can limit use, especially in the elderly and in patients with hepatic impairment. Side effects tend to be less with the secondary amines. Sedation is common because of its antihistamine effects but can be beneficial if there are sleep complaints. Anticholinergic side effects, which include dry mouth, constipation, urinary retention, and blurred vision, are also prevalent. Both anticholinergic and antihistamine side effects are dose dependent and can decrease with time; slow titration can improve compliance. Weight gain and sexual dysfunction are frequently reported. Cardiac side effects include orthostatic hypotension and dysrhythmias. Cardiac history should be reviewed, and a baseline electrocardiogram (ECG) should be considered for patients older than 40 years. Seizure thresholds are lowered. Risk of suicidal thinking and behavior is increased in children, adolescents, and young adults as old as 24 years. Further, if these medications are taken intentionally or accidentally in overdose, they are dangerous and can be extremely lethal at relatively low doses. When these medications are stopped, it is recommended that they be reduced by 25% per week to decrease side effects.

## Serotonin-Norepinephrine Reuptake Inhibitors

The SNRIs (venlafaxine, duloxetine, and milnacipran) also have analgesic properties. Together, they benefit in treating painful diabetic peripheral neuropathy, neuropathic pain, fibromyalgia, and, most recently, chronic musculoskeletal pain. Venlafaxine, the first drug in this class, is an inhibitor of serotonin reuptake at low doses, and at higher doses it inhibits norepinephrine reuptake. This means that it acts more like an SSRI at lower doses and does not become an SNRI until higher doses, at which point more side effects occur. Venlafaxine has some effectiveness with polyneuropathy,[79] including painful diabetic neuropathy[80] and fibromyalgia, but all of these indications are off-label.[81] Doses range from 75 to 225 mg/day. Milnacipran has been approved for use in fibromyalgia in the United States but not in Europe. A recent meta-analysis of five studies showed that this drug was superior to placebo, except for the side effect of sleep disturbance, in treating fibromyalgia.[82] Doses ranged from 25 to 200 mg/day. This same paper found four duloxetine studies that showed superiority of duloxetine to placebo in fibromyalgia except for fatigue symptoms.[82] Long-term benefit of 6 months has been shown with single daily doses of 60 or 120 mg per day of duloxetine for fibromyalgia. Starting doses are 20 to 30 mg in the morning. Duloxetine has also been approved to treat diabetic peripheral neuropathy, fibromyalgia, and generalized musculoskeletal pain in the United States. It is superior to placebo at doses between 60 and 120 mg per day with this disorder, and patients typically respond within the first week.[83] Last,

duloxetine is efficacious in treating chronic musculoskeletal pain, including discomfort from osteoarthritis and chronic lower back pain.[84]

### Side Effects

Side effects of all three of these SNRIs include nausea, dry mouth, and constipation. Sexual side effects tend to be less than with SSRIs. Duloxetine should not be used in patients with coexisting hepatic insufficiency. Milnacipran is not recommended for patients with end-stage renal disease but is unique in that it is not metabolized by cytochrome P450 isoenzymes. Patients with serotonin syndrome, caused by iatrogenic overstimulation of central and peripheral serotonin receptors, are seen with neuromuscular hyperactivity, autonomic hyperactivity, and altered mental status. It may occur abruptly and progress rapidly when these drugs are used at high doses or combined with other medications that stimulate serotonin. These drugs can also impair platelet aggregation, particularly if used concomitantly with aspirin or NSAIDs. Dose-related increases in blood pressure have been reported and should be followed. SNRIs carry a black box warning in the United States for increased risk of suicidal thinking and behavior in children, adolescents, and adults younger than 25 years. When these medications are discontinued, withdrawal symptoms have been reported. It is recommended that the dose be decreased by 25% per week to minimize these symptoms (see Tables 67-5 through 67-10).

## ANTI-CONVULSANTS

Neuropathic pain (NeP) is chronic pain initiated by nervous system lesions or dysfunction and maintained by a number of mechanisms. Excess stimulation of nociceptive pathways or damage to non-nociceptive pathways alters the balance between painful and nonpainful inputs so that pain results

CNS, Central nervous system.

without nociceptor stimulation. Several cellular and molecular mechanisms operating over different periods of time are thought to be involved in the abnormal peripheral and CNS activity associated with NeP.[85] Many of these mechanisms can be modulated by the anti-convulsants. First, nerve injury is reported to evoke spontaneous discharges from the cell bodies of myelinated fibers at the levels of the dorsal root ganglia. The mechanism of spontaneous activity is thought to be secondary to an increase in concentration of sodium channels in neuromas, dorsal root ganglion cells, and areas of demyelination.[86] Second, spinal inhibitory interneurons modulate the peripheral-to-central transmission of pain signals, thus "gating" ascending sensory information.[87] GABA and glycine and their receptors are abundant in the superficial dorsal horn,[88] but their levels are regulated by primary afferent input and change significantly after nerve injury.[88]

Finally, increased glutamatergic neurotransmission may also contribute to hyperexcitability and NeP through activation of both NMDA receptors and non-NMDA amino-3-hydroxy-5-methylisoxazole propionic acid (AMPA)/kainate-type glutamate receptors. Therefore drugs that modulate sodium channels, increase GABA, reduce glutamate release, or block glutamate effects can potentially reduce neuropathic pain.

The four main mechanisms of action of the anti-convulsants that result in pain reduction include[19] (1) calcium channel modulation, (2) sodium channel blockade, (3) NMDA antagonism, and (4) $GABA_A$ agonism. The net result of the mechanisms of action consists of reduced spontaneous pain and hypersensitivity through membrane stabilization, reduced neurotransmitter release, and reduced postsynaptic cellular activation in the dorsal horn of the spinal cord. Table 67-11 summarizes the mechanisms of action of the various anti-convulsants.

With the exception of pregabalin and gabapentin, studies on the efficacy of the various anti-convulsants to treat pain have been inconsistent. Pregabalin is FDA approved to treat postherpetic neuralgia (PHN), painful diabetic peripheral neuropathy (DPN), fibromyalgia, and pain related to

spinal cord injury; gabapentin is FDA approved to treat PHN; carbamazepine is FDA approved to treat trigeminal neuralgia; and valproic acid and topiramate are FDA approved to treat migraine headaches. The discussion in this chapter will focus on pregabalin and gabapentin, which have the most evidence in support of treating chronic neuropathic pain (Table 67-12).

## Mechanism of Action

Pregabalin and gabapentin are synthetic molecules that are structurally related to GABA. Both structures are derived by the addition of a cyclohexyl or branched-chain aliphatic carbohydrate moiety to the GABA backbone. However, the three-dimensional shapes of pregabalin and gabapentin are significantly different from GABA. The amine ($NH_2$) and carboxyl groups ($CO_2H$) are closer to each other than in the native GABA structure. It is proposed that this difference in the three-dimensional structure of pregabalin and gabapentin versus GABA accounts for their different pharmacologic activities.[90,91]

Although the exact mechanism of action of gabapentin and pregabalin is unknown, results from animal models suggest that pregabalin modulates neuronal hyperexcitability, resulting in analgesic and anticonvulsant effects. Reduction of neurotransmitter release occurs because pregabalin selectively binds to the $\alpha_2$-δ subunit of the N and P/Q subtypes of calcium channels of neurons in the brain and spinal cord, thereby modulating calcium influx into presynaptic cells.[92] Therefore there is less postsynaptic activation through the AMPA/kainite, NMDA, and neurokinin receptors. Unlike the opioids, which limit calcium influx via a G protein pathway, no tolerance is associated with pregabalin and gabapentin. Gabapentin and pregabalin do not have any effect on L-type calcium channels (e.g., verapamil); therefore there is no effect on blood pressure. New evidence suggests that gabapentin's site of action, unlike pregabalin, is at the locus coeruleus rather than the spinal dorsal horn. A recent study delivering gabapentin by the spinal route had no effect on pain.[18,93]

## Pharmacology of Gabapentin and Pregabalin

### Gabapentin

Gabapentin has a nonlinear bioavailability, with a reduction in absorption while the dose increases. This is the result of an active and saturable transport mechanism.[94] Gabapentin, 900 mg, has 60% bioavailability, and a 3600-mg dose has only 33% bioavailability. More frequent delivery of smaller doses may improve bioavailability through the saturable transport mechanism. It is less than 3% protein bound, and because of its high lipid solubility, it readily penetrates the CNS. Gabapentin is not metabolized and is excreted unchanged in the urine. Therefore renal impairment will significantly increase the drug half-life. Studies have shown efficacy at doses as high as 1800 mg and 2400 mg; however, doses higher than 1800 mg/day do not appear to be more efficacious. The current maximum FDA-approved dose to treat pain is 1800 mg/day. Because of its nonlinear kinetics, titration of gabapentin to an effective dose can be prolonged with an average onset of 10 to 14 days after initiation.

### Pregabalin

Pregabalin is not dependent on active transport for absorption and therefore has linear kinetics with bioavailability of approximately 90%. Unlike gabapentin, pregabalin absorption is independent of dose. It has negligible protein binding and readily penetrates into the CNS. Pregabalin is not metabolized and is excreted unchanged in the urine; therefore, renal impairment will significantly increase the drug half-life, and dose adjustments are required.[90] The effective dose of pregabalin is between 150 and 300 mg per day. Because of the linear kinetics and high bioavailability, the effective dose can be achieved in 2 to 3 days; therefore onset is faster than with gabapentin.

### Toxicity of Gabapentin and Pregabalin

Neither gabapentin nor pregabalin has any significant drug interactions, and protein binding is minimal. Because gabapentin and pregabalin have similar mechanisms of action, their side-effect profiles are very similar. The most common side effects with at least more than twice the incidence of placebo in controlled trials were dizziness, somnolence, dry mouth, peripheral edema, blurred vision, weight gain, and thinking abnormalities. Dizziness and somnolence usually began shortly after initiation of therapy, and most cases resolved with continued dosing. Dizziness and somnolence are dose related and can be reduced with slow titration. This side effect can also be an advantage when administered at night, in that it will improve sleep. Controlled studies with gabapentin and pregabalin have demonstrated improved patient sleep quality when compared with placebo.[19,95] Xerostomia (dry mouth) is dose dependent; however, it is

usually mild, and few withdrawals of patients from clinical trials have resulted from this side effect. Peripheral edema occurred in almost a third of participants in clinical trials. It does not appear to be dose related, nor is it associated with any cardiovascular, renal, or hepatic abnormalities. It is more common with the concomitant use of a thiazolidinedione antidiabetic agent.[96] Blurred vision is dose related and usually resolves with continued use. It is not associated with any ocular abnormalities. Weight gain has been reported to be as high as 8% of baseline weight but is not associated with any cardiac, renal, or hepatic abnormalities. A mildly increased appetite was reported in epilepsy and fibromyalgia trials. There is no association with baseline body mass index (BMI), gender, or age. Weight gain appears to plateau and is mild. Thinking abnormalities are typical of anti-convulsants and are consistent with the calcium channel modulation mechanism of these agents. Thinking abnormalities tend to be mild but can be bothersome enough in some patients to lead to discontinuation.

Anti-convulsants, including gabapentin and pregabalin, have approximately twice the risk of suicidal ideation versus placebo. This increased risk is not age related, and appears to occur at between 1 and 24 weeks of therapy. Patients should be warned of this side effect and instructed to contact their health care provider immediately if it occurs.

Studies with pregabalin have shown a mild PR interval prolongation that was not associated with increased risk of second- or third-degree atrioventricular block. Pregabalin may result in a mildly decreased platelet count, which is not associated with an increase in bleeding-related adverse events. Pregabalin may also result in mild elevations in creatinine kinase, which are asymptomatic in most patients.

In controlled clinical trials of pregabalin, more patients reported euphoria as compared with placebo. In a follow-up drug likability study in recreational drug users of sedative-hypnotics, pregabalin participants reported a "good drug effect," "a high," and "liking" to a degree that was similar to 30 mg of diazepam. In addition, clinical studies showed withdrawal symptoms of insomnia, nausea, headache, and diarrhea. Therefore the FDA approved the drug with a category V controlled substance schedule. Although pregabalin is Schedule V, it has very low abuse potential. As with any anticonvulsant therapy, pregabalin and gabapentin should be withdrawn slowly during at least a week to avoid withdrawal symptoms (Figure 67-3).

## MUSCLE RELAXANTS

Patients frequently describe muscular pain as "spasms," and clinicians clearly know that loss of range of motion is detrimental to their patients. It makes sense that a medicine that acts as a muscle relaxant would be of great value in treating patients with these complaints. Unfortunately, skeletal muscle relaxants do not have a primary role in the treatment of chronic pain because of limited true effects on muscles, significant side effect profiles, drug interactions, or addiction potential.

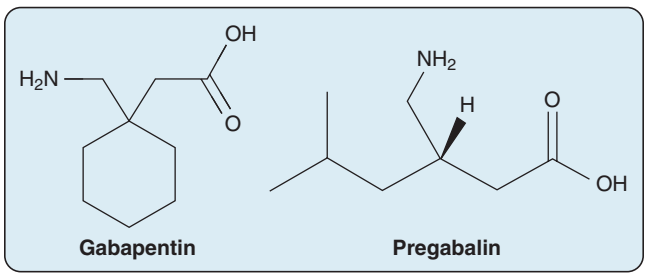

**Figure 67-3** Chemical structures of pregabalin and gabapentin.

The list of medications classified as skeletal muscle relaxants is highly diverse (Figure 67-4). Because each of the drugs in this class has a unique mechanism of action and side effect profile, each medication from this class must be examined separately. Adding to the difficulty of understanding these medications is the lack of consensus as to how or why they provide benefit. The two approved clinical indications are for treatment in upper motor neuron diseases that result in spasticity and in peripheral musculoskeletal disorders that cause pain and spasms. Each of these medications can thus be classified as an antispastic or antispasmodic agent. These medications should not be used as first-line medications and usually should be used in conjunction with other pain medications. In addition, most antispasmodic medications come with restriction of use to 2 to 3 weeks. Despite this, many skeletal muscle relaxants are prescribed on a long-term basis for chronic conditions.[97]

Understanding the reflex arc in muscle is important in understanding where these agents act. The simplest reflex is monosynaptic. A muscle spindle transmits an efferent signal through the Ia afferent neuron; this enters the dorsal horn of the spinal cord and synapses on an alpha motoneuron. This neuron then exits the spinal cord through the ventral root and innervates the extrafusal fibers of the same muscle, causing a contraction in the muscle. The Ia afferent signal is also transmitted polysynaptically through interneurons that inhibit alpha motoneurons of antagonist muscles, causing them to relax. Gamma motoneurons located in the ventral horn adjust the sensitivity of the muscle spindles to stretch. They travel with the alpha motoneurons and receive input from cutaneous receptors and many supraspinal pathways, including the corticospinal and reticulospinal tracts. Polysynaptic spinal reflexes with supraspinal connections are much more abundant than monosynaptic reflexes. These connections are both excitatory and inhibitory, providing improved control and feedback to set and fine-tune motor tone. The main tract that inhibits spinal reflexes is the dorsal reticulospinal tract, and the main excitatory pathway is the bulbopontine tegmentum.[98]

Spasticity occurs in upper motoneuron disorders, such as multiple sclerosis, spinal cord injuries, traumatic brain injuries, strokes, and cerebral palsy. These diseases cause loss of descending inhibition from the brain to the spinal cord, leading to muscular hypertonicity and increased resistance to stretch. This presentation, which is classically described as a "clasp-knife phenomenon," tends to affect the flexors of the upper extremities and the extensors of the lower extremities more than other muscle groups. Medications approved for spasticity include baclofen, dantrolene, tizanidine, and diazepam.

The antispasmodic agents are used to treat muscle pain and spasms when hypertonicity, hyper-reflexia, or other signs of upper motoneuron disorders are not present. This presentation is much more common than spasticity and would include syndromes such as fibromyalgia, tension

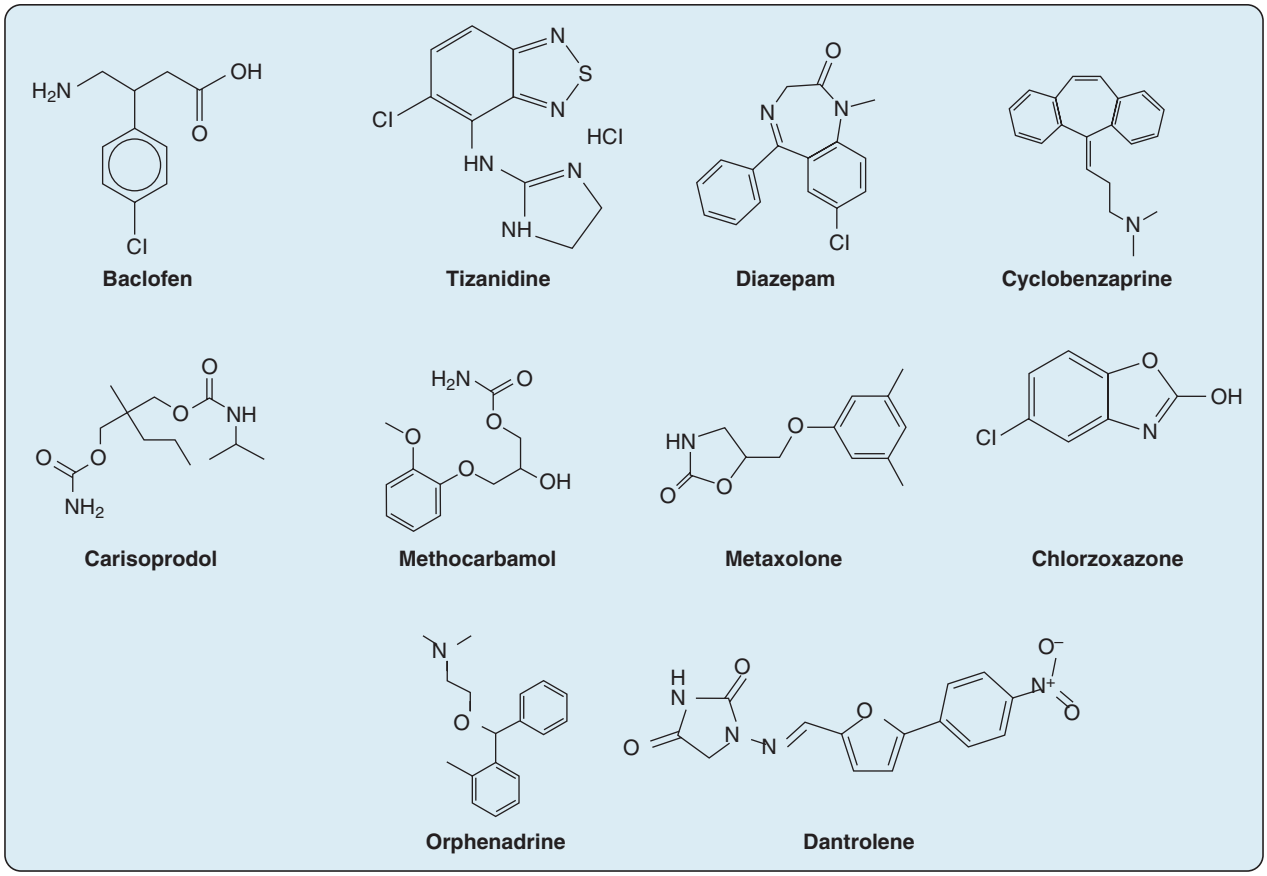

**Figure 67-4** Chemical structures of muscle relaxants.

headaches, myofascial pain disorders, and nonspecific back pain. Medications include cyclobenzaprine, carisoprodol, metaxalone, chlorzoxazone, methocarbamol, and orphenadrine. Tizanidine and benzodiazepines are approved for both spasticity and musculoskeletal disorders. How each of these drugs improves these conditions is not completely clear, but the nonspecific sedative effects may have greater importance than the effects on muscles or spinal reflexes.

## Antispasmodic Medications

### Baclofen

Baclofen blocks pre-synaptic and postsynaptic $GABA_B$ receptors[99] and disrupts polysynaptic and monosynaptic reflexes at the spinal cord level.[99] Oral doses usually start at 5 mg, three times per day, with a maximum dose of 80 mg per day. This medication frequently can be used intrathecally for the same indication with a reduction in clinical side effects. Sedation, weakness, hypotension, nausea, depression, and constipation have been reported. Taper slowly and adjust for renal impairment. Withdrawal symptoms include hallucinations, seizures, and pruritus.

### Dantrolene

Dantrolene acts directly on the muscle by decreasing the release of calcium from skeletal muscle sarcoplasmic reticulum.[101] It has a black box warning about hepatotoxicitiy.[102] Its risk is much greater with patients taking 800 mg per day or more compared with doses of 400 mg per day. It is recommended that the patient stop this medication after 45 days if no benefit is derived.

### Tizanidine

Tizanidine is a centrally acting agonist of the $\alpha_2$ receptor[103] that reduces the release of excitatory amino acids from the pre-synaptic terminal of spinal interneurons.[104] This reduces tonic stretch reflexes and polysynaptic reflex activity.[105] Doses start at 2 to 4 mg at night and increase by 2 to 4 mg three to four times per day with a maximum dose of 36 mg per day. Side effects include hypotension, sedation, and dry mouth. Its major route of elimination is renal, and renal impairment can significantly decrease clearance. It is metabolized via CYP1A2, and concomitant use with ciprofloxacin or fluvoxamine is contraindicated.[106] Elevated liver functions—three times the upper level of normal—have occurred in 5% of patients.[106] Monitoring of liver function is recommended. Acute withdrawal can cause hypertension, tachycardia, and hypertonia. Use with alcohol should be warned against, and oral contraceptives will decrease clearance with doses as low as 4 mg per day.

### Diazepam

Diazepam works by central blockade of $GABA_A$,[101,107] which is an inhibitory neurotransmitter in the CNS. It was the

first drug used to treat spasticity and is often used to compare new agents in clinical trials. Efficacy for spasticity and muscle pain is believed to be similar to that of benzodiazepines as a class.[108] Clinical trials showing efficacy with benzodiazepines are based on tetrazepam, which currently is not available in the United States.[109] It is not considered a first-line agent for spasticity or muscle pain because of its sedative effects, drug interactions, and significant abuse potential.

## Antispasmodic Medications

### Cyclobenzaprine

Cyclobenzaprine is structurally related to tricyclic antidepressants and thus causes sedation through its anticholinergic effects. It acts primarily at the brain stem to reduce tonic somatic motor activity influencing both gamma and alpha motoneurons. Dosing at 5 mg, three times per day, has similar efficacy when compared with 10 mg, three times per day, with reduced side effects.[110] The maximum daily dose is 30 mg. This medication also comes in 15- and 30-mg extended-release formulations. Concomitant use with MAO inhibitors is contraindicated. This drug should not be used during the acute recovery phase of myocardial infarction, or in patients with arrhythmias, heart block, congestive heart failure, or hyperthyroidism. The risk of seizures with tramadol is increased if this medication is added.[111] The risk of serotonin syndrome can be increased in patients taking SSRIs.[112]

### Carisoprodol

Carisoprodol in animal studies has shown muscle relaxation through altered interneuronal activity in the spinal cord and in the descending reticular formation of the brain. It is metabolized in the liver to meprobamate, a Schedule IV medication with abuse potential.[113] Meprobamate binds to $GABA_A$ receptors, which results in further sedation. Doses start at 250 mg, as often as four times per day, with a maximum dose of 1400 mg per day. It is contraindicated in patients with a history of acute intermittent porphyria. CYP1C19 inhibitors such as omeprazole or fluvoxamine may increase carisoprodol levels and decrease meprobamate. CYP1C19 inducers such as rifampin or St. John's wort increase exposure to meprobamate.

### Methocarbamol

Methocarbamol, a carbamate derivative of guaifenesin, is a CNS depressant with no direct action on striated muscle, the motor end plate, or the nerve fiber. It comes in 500- and 750-mg tablets and can be given as many as four times per day, with a maximum dose of 8 g per day. The parenteral form has been associated with skin sloughing and thrombophlebitis. It should be used with caution in patients with myasthenia gravis receiving anti-cholinesterase agents.

### Metaxalone

Metaxalone also has no direct actions on muscles. Its effects occur mainly through generalized CNS depression. It tends to cause much less sedation than other drugs in this class, and has limited drug interactions. It is contraindicated in drug-induced, hemolytic anemias and in significantly impaired renal or hepatic function. The dose most commonly used is 800 mg, three or four times per day.

### Chlorzoxazone

Chlorzoxazone is a centrally acting agent that acts primarily at the level of the spinal cord and subcortical areas of the brain, where it inhibits multisynaptic reflex arcs. Doses are 250 to 750 mg, three or four times per day. Hepatocellular toxicity has been reported with this drug.

### Orphenadrine

Orphenadrine is derived from diphenhydramine. It does not directly relax muscles and possesses greater anticholinergic properties than diphenhydramine. Its dosage recommendation is 100 mg, twice a day. It is contraindicated in patients with glaucoma, pyloric, or duodenal obstruction, stenosing peptic ulcers, prostatic hyperplasia or obstruction of the bladder neck, cardiospasm (megaesophagus), and myasthenia gravis.

### Efficacy

Clinical studies with these drugs are very limited, poorly controlled, and of short duration. One meta-analysis[114] found fair evidence that tizanidine and baclofen are roughly equivalent and are similar to diazepam for the treatment of spasticity. Investigators also state that data on efficacy for muscle relaxants with musculoskeletal conditions are limited, but for treatment compared with placebo, cyclobenzaprine, tizanidine, carisoprodol, and orphenadrine show a consistent trend favoring active treatment. Data demonstrating effectiveness for chlorzoxazone, methocarbamol, baclofen, and dantrolene are limited. Last, data for metaxalone are mixed.

# EMERGING TARGETS

## Nerve Growth Factor Inhibitors

Nerve growth factor (NGF) is a ligand to the tyrosine kinase (TrKA) receptor located on sensory neurons. Inflammation results in increased levels of NGF, which stimulate the TrKA receptor and lead to an increase in inflammatory mediators and increased sensitivity to pain. Overexpression of NGF also leads to a proliferation of sympathetic fibers, which may be important in the production of inflammatory and neuropathic pain. Because NGF is essential for the survival and development of sensory neurons, NGF inhibitors may lead to peripheral nerve dysfunction and neuropathies. Tanezumab, a recombinant humanized monoclonal antibody targeting NGF, is in phase II trials and is under development to treat pain associated with osteoarthritis, low back pain, and metastatic bone cancer.[115] In 2010, the FDA halted all clinical trials for this entire class of drug because of reports that the drugs are associated with osteonecrosis. In 2012, an advisory panel to the FDA voted unanimously to allow the trials to continue but without

concomitant use of NSAIDs, because patients on NSAIDs had greater joint damage. Studies using tanezumab in osteoarthritis of the knee and hip are promising. Tanezumab combined with NSAIDs is better than anezumab monotherapy; however, there are more adverse events with the combination therapy.[116,117]

## Cannabinoid Agonists

Cannabinoid receptors type 1 (CB1) are located at multiple locations in the peripheral and central nervous system, whereas CB2 receptors are located on inflammatory cells (monocytes, B/T cells, mast cells). CB2 activation results in a reduction in inflammatory mediator release, plasma extravasation, and sensory terminal sensitization. Activation of peripheral CB1 receptors results in a reduction in the release of pro-inflammatory terminal peptides and a reduction in terminal sensitivity. Activation of central CB1 receptors leads to reduced dorsal horn excitability and activates descending inhibitory pathways in the brain. The net result is a reduction in both pain and hyperalgesia. Inhaled cannabis has been extensively studied in various pain syndromes with mixed results. More recent well-controlled trials in neuropathic pain have shown promise.[118] Sativex is a sublingual spray containing a mixture of tetrahydrocannabinol and cannabidiol, which failed to reach the primary efficacy endpoint in a phase III cancer pain trial. Studies with cannabis in musculoskeletal pain are limited; however, it has been shown to reduce the pain of rheumatoid arthritis and chronic pain of various other causes.[119]

## AMPA/Kainate Antagonists

Glutamate, an excitatory amino acid neurotransmitter, has been implicated in pain perception. Two types of glutamate receptors are found in the CNS: ionotropic and metabotropic. Ionotropic receptors are further functionally categorized into NMDA and non-NMDA receptor subtypes (2-amino-3-[3-hydroxy-5-methylisoxazol-4-yl]propionic acid [AMPA] and kainate receptors).[120] AMPA and kainate receptors are prevalent within the dorsal horn of the spinal cord, and activation is thought to mediate rapid excitatory neurotransmission, resulting in central sensitization mechanisms. Tezampanel, an intravenously administered antagonist of AMPA and kainate receptors, has been shown to be effective in reducing human experimental pain.[121] NGX426, an oral prodrug of tezampanel, has been shown in experiments to be effective in reducing human pain.[122]

## Angiotensin II Type 2 Receptor Antagonists

Angiotensin II type 2 receptors (AT2) are expressed on small fibers and the dorsal root ganglion. Angiotensin converting enzyme inhibitors have failed to show any effects on pain, and attention has been directed at the more specific type 2 receptors. A phase II study with EMA-401 (an AT2 receptor antagonist) in postherpetic neuralgia in 183 participants resulted in significant reductions in the primary outcome measure of pain intensity. Patients responses on secondary outcome measures of pain relief onset, 30% and 50% responder rate, McGill pain questionnaire, and Patient Global Impression of change were also positive. The drug appears to be safe and well tolerated.[123]

CHAPTER 68

# Nutrition and Rheumatic Diseases

Lisa K. Stamp • Leslie G. Cleland

**KEY POINTS**

- Nutritional factors can have pro-inflammatory effects, anti-inflammatory effects, or both.
- Nutritional factors have been implicated in the etiology of a variety of rheumatic disorders, including gout and rheumatoid arthritis (RA).
- Many patients with rheumatic disease believe diet plays an important role in their symptoms.
- Dietary supplementation with omega-3 fatty acids can reduce signs and symptoms of inflammation, as well as reduce the need for escalation of treatment with disease-modifying anti-inflammatory drugs and the use of nonsteroidal anti-inflammatory drugs (NSAIDs) in patients with RA.
- RA, systemic lupus erythematosus, gout, and NSAID use have been linked to increased risk for thrombotic cardiovascular events. Fish oil supplements have been associated with improvement in multiple aspects of cardiovascular health and reduction in cardiac death.

Nutrition plays a role in the management of most chronic diseases. Physicians provide dietary advice to patients with diabetes, heart disease, and obesity as part of standard clinical care. Although the role of diet and nutrition is well established in the etiology and management of gout, the role of nutrition in other rheumatic diseases, such as rheumatoid arthritis (RA), is less well accepted. In general, dietary advice is not part of standard clinical practice for patients with inflammatory rheumatic diseases. Despite a widespread lack of conviction among physicians about the role of nutrition, many people with arthritis believe food plays an important role in their symptom severity, and approximately 50% will have tried dietary manipulation in an attempt to improve their symptoms.[1]

It is well recognized that inflammatory disease processes can interfere with nutritional status. The impact of nutritional factors on the inflammatory response has also been recognized. Furthermore, diets and lifestyles have changed considerably through industrialization, with significant effects on rates of obesity, food choices, and consumption of different dietary components. In light of this, the role nutrition in the etiology and management of rheumatic diseases is becoming increasingly important.

## NUTRITION AND THE INFLAMMATORY PROCESS

**KEY POINTS**

- Omega-3 fatty acids are immunoregulatory.
- Vitamin D has multiple immunosuppressive effects.
- Antioxidants can be acquired through the diet.
- Adipose tissue is metabolically active and has effects on the inflammatory response.
- Probiotics have anti-inflammatory properties.

### Role of Omega-3 Fatty Acids and the Inflammatory Process

#### Fatty Acid Biochemistry

Fatty acids are divided into three groups on the basis of the number of double bonds they contain. Saturated fatty acids have no double bond, monounsaturated fatty acids have one double bond, and polyunsaturated fatty acids (PUFAs) have two or more double bonds. C18 fatty acids are prominent in the diet and provide the index fatty acids for the above classification. PUFAs are further grouped according to the site of the double bond proximal to the methyl (omega) terminus as n-6 or n-3. Vertebrates do not have the enzymes required to introduce double bonds in the n-3 and n-6 positions; therefore these fatty acids must be obtained from the diet. Thus they are known as *essential fatty acids*.

In general, the Western diet contains more n-6 fats than n-3 fats because of the dominance in processed foods and the visible fats of soybean, safflower, sunflower, and corn oils, which contain the n-6 fat linoleic acid (LA; 18:2n-6). The n-3 homologue of LA, α-linolenic acid (ALA; 18:3n-3), is present in flaxseed oil, which is generally a minor dietary component. LA and ALA may be used in energy metabolism or be converted to the C20 fatty acids arachidonic acid (AA) and eicosapentaenoic acid (EPA), respectively. AA and EPA are then incorporated into cell membranes and tissues. EPA can be further metabolized to the n-3 fatty acid docosahexaenoic (DHA).

The critical process linking fatty acids and inflammation is the metabolism of AA and EPA to eicosanoids, which act

as inflammatory mediators. AA is metabolized via cyclooxygenase (COX) to n-6 eicosanoids (prostaglandin [PG] $E_2$, thromboxane [TX] $A_2$ or via 5-lipoxygenase [5-LOX] to n-6 leukotrienes [LTs]). Through the same pathways, EPA is metabolized to n-3 PGs and LTs, respectively. In comparison to the n-6 eicosanoids produced from AA, EPA is a poor COX substrate such that n-3 PGs are not as readily produced (Figure 68-1). EPA and DHA competitively inhibit production of most n-6 eicosanoids; prostacyclin ($PGI_2$) is an exception. Increased dietary consumption of n-3 fatty acids such as EPA increases the proportion of EPA incorporated in cellular membranes and tissues, partly at the expense of AA incorporation. The net result is an alteration in the balance of n-3/n-6 eicosanoid production (see Figure 68-1). EPA and DHA can also be metabolized through lipid oxygenase pathways to novel specialized pro-resolving lipid mediators (SPMs) of inflammation (see later).

### Pro-inflammatory Actions of Eicosanoids

In general, the n-6 eicosanoids ($PGE_2$ and $TXA_2$) are pro-inflammatory, whereas the n-3 eicosanoids are either less potent in their effects ($TXA_3$) or less abundant ($PGE_2$). $TXA_2$ promotes interleukin (IL)-1β and tumor necrosis factor (TNF) production by mononuclear cells,[2] whereas $PGE_2$ results in vasodilatation, increased vascular permeability, and hyperalgesia (see Figure 68-1). $PGE_3$ is edemagenic, although little is produced. $LTB_5$ is 10 to 30 times less potent than $LTB_4$ as a neutrophil chemotaxin.

### Effect of n-3 Fatty Acids on Pro-inflammatory Cytokine Production

IL-1β and TNF production may be reduced as a consequence of dietary n-3 fatty acid supplementation. Although some of this cytokine inhibition is mediated through effects on eicosanoids, there also appears to be eicosanoid-independent cytokine inhibition. Fatty acids may have direct effects on intra-cellular signaling mechanisms, including nuclear factor-κB (NF-κB) and peroxisome proliferator–activated receptor (PPAR)-γ, thereby affecting cytokine production.[3] There are also effects on the inflammasome, a protein complex that has a central role in control of the immune system. The NLRP3 inflammasome is activated by a variety of stimuli, including pathogenic organisms and monosodium urate crystals, that lead to production of IL-1β and IL-18.[4] n-3 Fatty acids have recently been shown to inhibit NLRP3-dependent caspase activation and IL-1β production.[5]

### Effects of n-3 Fatty Acids on Major Histocompatibility Expression

The number of major histocompatibility (MHC) molecules expressed on antigen-presenting cells (APCs) is an important determinant of T cell response to antigen. Patients with RA have high levels of class II MHC expression on T cells and synovial lining cells.[6] In vitro studies show that EPA and/or DHA reduces monocyte expression of human leukocyte antigen (HLA)-DR and HLA-DP molecules and reduces the ability of monocytes to present antigen to autologous lymphocytes.[7] Thus n-3 fatty acids may have an anti-inflammatory effect via suppression of pathogenic T cell activation through inhibition of APC function. A more recent murine study has shown that fish oil also has effects on MHC molecules on B cells and T cell organization at the immunologic synapse.[8]

### Effect of n-3 Fatty Acids on Adhesion Molecule Expression

Adhesion molecules expressed on endothelial cells and leukocytes mediate the transit of cells from the circulation into tissues. Intercellular adhesion molecule-1 (ICAM-1) and its cognate receptor, leukocyte function-associated antigen (LFA)-1, have been shown to be important in migration of leukocytes into inflamed synovium in animal models.[9] ICAM-1 blockade has also been reported to reduce disease activity in RA.[10] In vitro n-3 fatty acids decrease human monocyte ICAM-1 and LFA-1 expression.[7] In addition, dietary n-3 fatty acid supplementation reduces soluble ICAM-1 and vascular cell adhesion molecule-1 (VCAM-1) plasma concentrations.[11]

### Effect of n-3 Fatty Acids on Degradative Enzymes

Proteinases have a pivotal role in cartilage degradation and bone erosion. n-3 Fatty acids added in vitro can suppress proteinases a disintegrin and metalloproteinase (ADAM family) with thrombospondin-1 domains (ADAMTS)-4, ADAMTS-5, and matrix metalloproteinase (MMP)-3 in IL-1α-stimulated bovine chondrocytes.[12] This inhibition of chondrocyte proteases is a mechanism through which n-3 fatty acids may inhibit cartilage degradation and bone erosion.

The receptor activator of NF-κB (RANK)/ligand (RANKL)/osteoprotegerin (OPG) pathway is also important in bone pathophysiology in RA. Increased RANK/RANKL and decreased OPG contribute to bone erosion. Three months of dietary fish oil supplementation has been reported to decrease the RANK/OPG ratio, which may help prevent bone resorption that leads to erosions.[13]

### Importance of the Balance of n-3 and n-6 Fatty Acids in the Inflammatory Process

The balance of AA and EPA can be altered through dietary fatty acid intake. In humans, the conversion of dietary ALA to tissue EPA is inefficient and fish/fish oils are a more effective way to increase EPA and DHA in tissues. Changes in AA/EPA ratios in tissues have downstream effects on eicosanoid production and the resulting pro-inflammatory/anti-inflammatory environment. Dietary supplementation with fish oil in humans results in decreased production of $PGE_2$,[14] $TXA_2$,[14] and $LTB_4$[15] with increased production of $TXA_3$[16] and $LTB_5$.[17] These data provide a mechanistic basis for beneficial effects of dietary n-3 fatty acid supplementation in the control of inflammatory diseases. Dietary fish oil supplements have been shown to increase vascular production of prostacyclin ($PGI_2$).[18] Although the role of $PGI_2$ in inflammation is not well defined, it is a potent vasodilator and inhibits platelet aggregation, as well as disaggregating platelets. These effects favor maintenance of

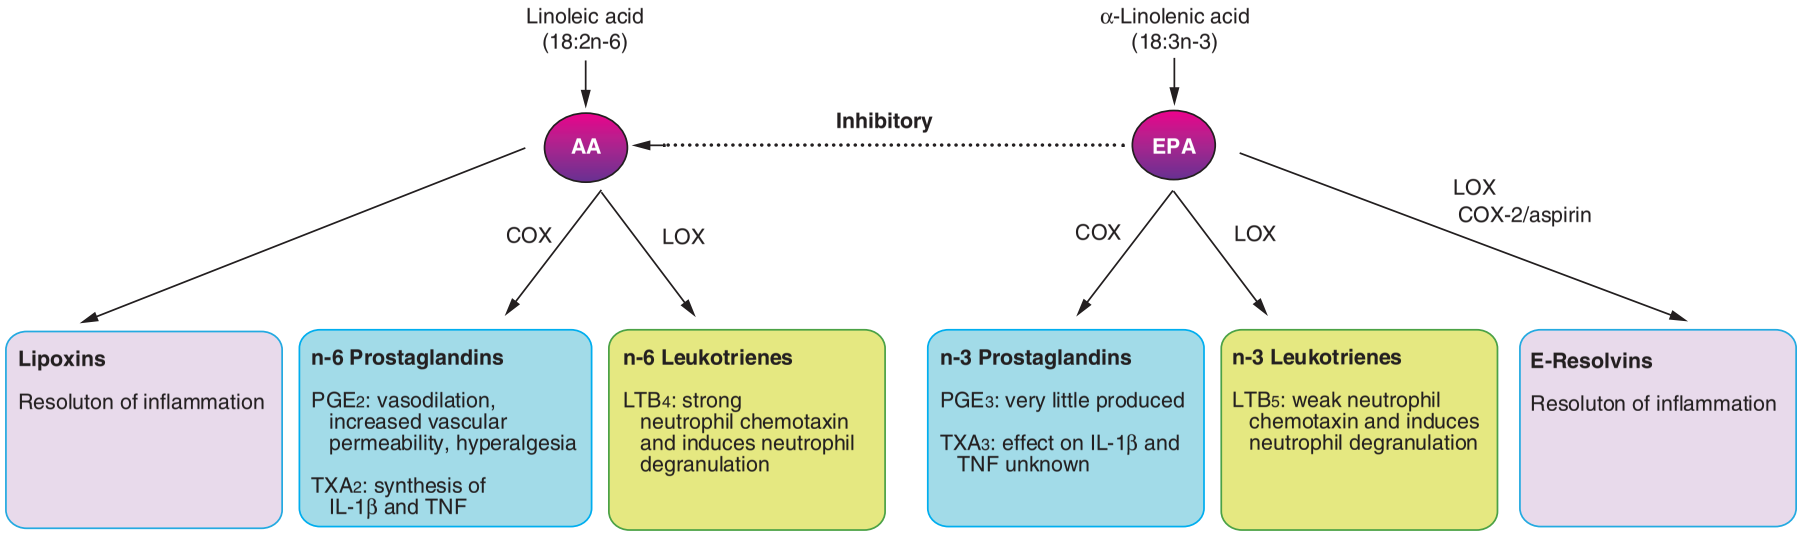

**Figure 68-1** Metabolism of linoleic acid and α-linolenic acid to n-6 and n-3 prostaglandins and leukotrienes. vascular patency. Importantly, patients with several of the major rheumatic diseases (e.g., RA, systemic lupus erythematosus [SLE] and gout) are at high risk for serious cardiovascular events and mortality, to which nonsteroidal anti-inflammatory drug (NSAID)–associated COX-2 inhibition may contribute.

## SPECIALIZED PRORESOLVING MEDIATORS AND N-3 FATTY ACIDS

It has recently been recognized that resolution of inflammation is an active rather than passive process. SPMs, which include lipoxins, resolvins, protectins, and maresins, synthesized from the n-3 fatty acids EPA and DHA, have an important role in this process (Table 68-1). SPMs are formed through the actions of multiple lipid oxygenases (LO), including 5-LO and COX-2, with the yield of some SPMs increased by acetylation of COX-2 by aspirin (see Figure 68-1). Resolvins derived from EPA are known as *E-resolvins*, whereas those derived from DHA are known as *D-resolvins*. Production of resolvins can be increased by dietary n-3 fatty acid supplementation.[19] The resolvins have a variety of anti-inflammatory actions, including inhibition of TNF and IL-1β production and inhibition of human polymorphonuclear leukocyte transendothelial migration.[20] Resolvins have been shown to reduce pain and joint stiffness but not joint/paw edema in adjuvant-induced arthritis.[21] SPMs have been detected in synovial fluid from patients with RA, suggesting that these mediators may have local anti-inflammatory effects.[22] The presence and role of SPMs in other inflammatory rheumatic diseases has not been investigated to date.

### Vitamin D and the Inflammatory Process

Vitamin D has multiple immunosuppressive effects in addition to its effects on bone and calcium metabolism. The biologically active form of vitamin D (1,25-dihydroxyvitamin $[OH]_2D_3$) interacts with vitamin D receptors, which are expressed on a variety of cells, including osteoblasts, T cells, dendritic cells (DCs), macrophages, and B cells. These cells also have the capacity to convert more abundant $25(OH)D_3$ to $1,25(OH)_2D_3$ and to degrade $1,25(OH)_2D_3$. Accordingly, the molecular machinery is in place for important autocrine and paracrine effects of vitamin D at sites of inflammation.

DCs have a central role in activation of the immune system and in response to self. $1,25(OH)_2D_3$ inhibits the differentiation of monocyte precursors into mature DCs, down regulates expression of class II MHC molecules on DCs, inhibits IL-12 production, and promotes DC apoptosis, thereby inhibiting DC-dependent T cell activation.[23,24] In addition, $1,25(OH)_2D_3$ can promote DC expression of tolerizing functions, which instruct T regulatory (Treg) cells, which in turn may inhibit the development of autoimmunity.[25]

Vitamin D inhibits monocyte/macrophage pro-inflammatory cytokine production, including TNF, IL-6, and IL-1α.[26,27] Vitamin D has direct effects on T cells, in particular inhibition of proliferation and cytokine production by T helper (Th)1 cells, and may enhance Th2 cytokine production.[28] $1,25(OH)_2D_3$ has also been shown to reduce Th17 cell differentiation through its effects on DCs, as well as direct effects on Th17 cells that lead to inhibition of IL-17A, IL-21, IL-22, and IFN-γ production and enhancement of FOXP3, cytotoxic T lymphocyte–associated antigen (CTLA)-4, and IL-10.[25,29] Importantly, the more abundant, weakly active form of vitamin D, $25(OH)D_3$, can be converted by DCs to potently active $1,25(OH)_2D_3$, with consequent alteration in T cell responses toward an anti-inflammatory phenotype, which is characterized by high CTLA-4 and reduced IL-17, IFN-γ, and IL-21 production.[30] Thus the level of free $25(OH)D_3$ available to DCs may have a pivotal role in determining the balance between T cell inflammatory and regulatory responses.[30]

$1,25(OH)_2D_3$ inhibits the proliferation of activated B cells, induces activated B cell apoptosis, and inhibits plasma cell differentiation and immunoglobulin secretion.[31] Thus vitamin D deficiency may have a role in the etiology of B cell–mediated autoimmune disorders, whereas vitamin D supplementation may have beneficial effects in B cell–mediated autoimmune diseases, such as SLE and RA.

The array of relevant effects of vitamin D on the immune system suggests that vitamin D status may be important with regard to the etiology and management of rheumatic diseases more generally.

### Reactive Oxygen Species/Antioxidants and the Inflammatory Process

Production of reactive oxygen species (ROS), such as superoxide and hydrogen peroxide, are part of the

normal immune response. Acting through transcription factors such as NF-κB, ROS increase production of pro-inflammatory eicosanoids and cytokines, including $PGE_2$, TNF, and IL-1β. Thus unchecked production of ROS may cause inflammation and tissue damage. Antioxidant enzymes such as superoxide dismutase and glutathione peroxidase remove superoxide, thereby providing protection from oxidative damage. Vitamin C (ascorbic acid), vitamin E (α-tocopherol), and β-carotene are acquired through the diet and can act as ROS scavengers.

## Obesity and the Inflammatory Process

With excess energy intake and reduced energy expenditure, body weight and adiposity increase. Obesity (body mass index [BMI] >30 kg/m$^2$) is a significant health problem globally. The World Health Organization estimates that by 2015, approximately 2.3 billion adults will be overweight, and more than 700 million will be obese.

Adipose tissue was originally thought to be simply a fat store. However, it is now recognized that adipose tissue and adipocytes are metabolically active and contribute to systemic inflammatory responses (Figure 68-2). Adipocytes release the pro-inflammatory cytokines TNF, IL-1β, and IL-6. IL-6 enters the systemic circulation and increases C-reactive protein (CRP) and serum amyloid A production by the liver.

Adipocytes produce adipokines: leptin, resistin, and visfatin (pro-inflammatory), and adiponectin (anti-inflammatory) (see Figure 68-2). Although the primary function of

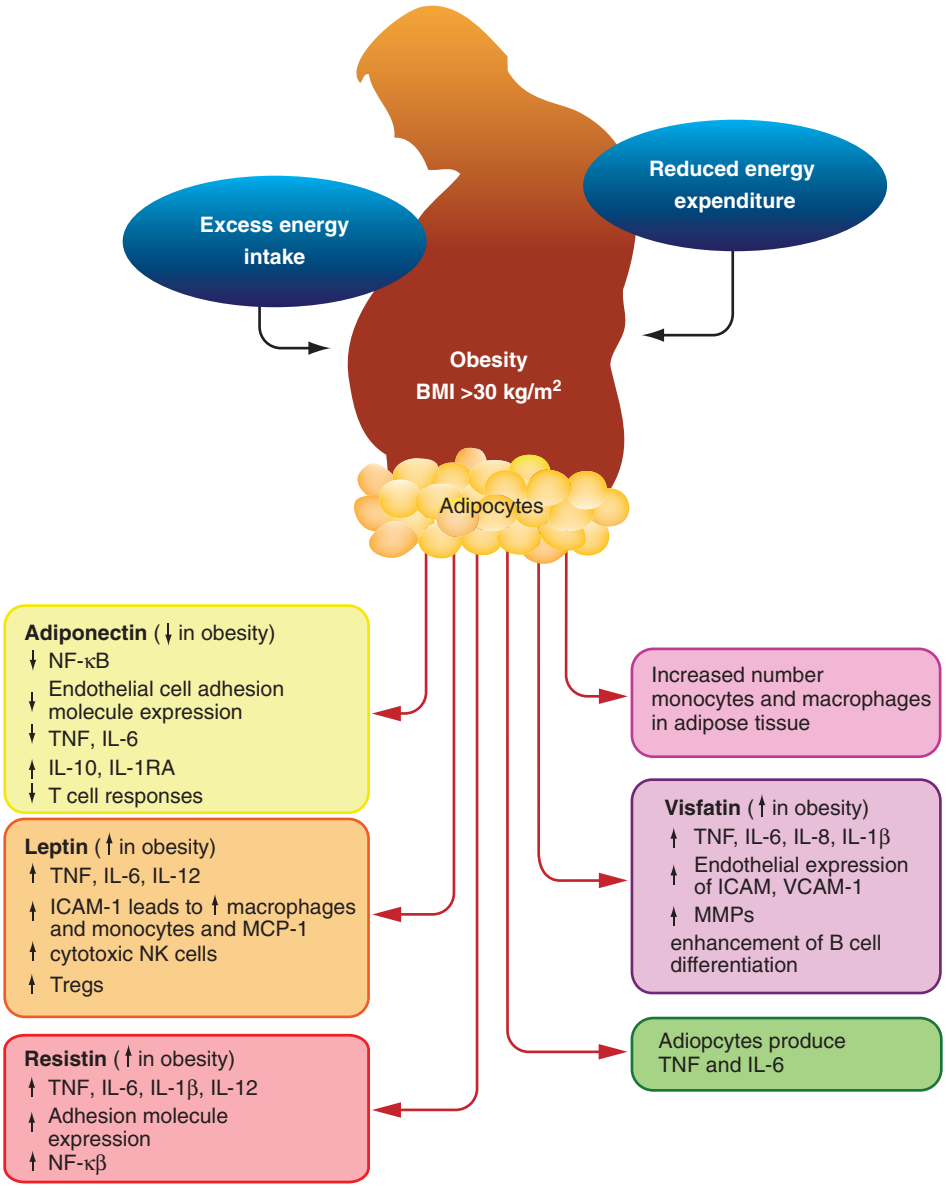

**Figure 68-2** Inflammatory mechanisms of obesity. BMI, Body mass index; ICAM, intercellular adhesion molecule; IL, interleukin; MCP-1, monocyte chemotactic protein-1; MMPs, matrix metalloproteinases; NF-κB, nuclear factor-κB; NK, natural killer; Th, T helper; TNF, tumor necrosis factor; VCAM-1, vascular cell adhesion molecule-1.

leptin is appetite control, it also has a number of pro-inflammatory actions. Leptin increases the expression of adhesion molecules such as ICAM-1 and monocyte chemoattractant protein (MCP)-1, thereby favoring recruitment of monocytes/macrophages into adipose tissue. Leptin also increases IL-1β, TNF, and IL-6 production by monocytes/macrophages. Leptin increases proliferation of Th1 cells, and inhibits proliferation of Th2 cells and Treg cells. By contrast, adiponectin has anti-inflammatory effects, which include inhibition of TNF-induced adhesion molecule expression and inhibition of NF-κB, a pivotal intra-cellular factor in activation of inflammatory responses. Adiponectin also reduces production of TNF and IL-6 while promoting production of the anti-inflammatory cytokines IL-10 and IL-1RA. Adiponectin also increases the number of Tregs. Production of adiponectin is inhibited by TNF, which thereby helps sustain the pro-inflammatory alteration of homeostasis found in obesity. Resistin is produced by mononuclear cells and adipocytes. Resistin increases macrophage/monocyte and adipocyte production of TNF, IL-6, and IL-1β, and also increases expression of the adhesion molecules ICAM-1, VCAM-1, and MCP-1.[32] Visfatin, which is produced by lymphocytes and adipocytes, has similar pro-inflammatory effects, including induction of IL-8, IL-6, IL-1β, and TNF; increased endothelial expression of ICAM-1, VCAM-1, and MMPs; and enhancement of B cell differentiation.[32] The net result of obesity is thus an inflammatory state associated with an increase in circulating CRP.

## Probiotics and the Inflammatory Process

Probiotics are defined as live microorganisms, which confer a health benefit to the host. The most common probiotics are lactobacilli and bifidobacteria. These organisms are present in foods, often dairy fermented products such as yogurt, as well as in supplements such as probiotic drinks in lyophilized form. Probiotics have anti-inflammatory properties; the mechanism of anti-inflammatory action varies among different probiotics species and different species strains. Thus, although certain probiotic strains may confer health benefits, these benefits may not be seen with other probiotic species or strains.

Probiotics may exert their putative anti-inflammatory effects by interacting with intestinal epithelial cells. Resultant modulation of intestinal microflora and fortification of intestinal barrier function may lead to altered exposure of the immune system to microbes and direct effects on immune cells within the intestine. Associated effects relevant to anti-inflammatory responses include accumulation of $CD4^+$ Treg cells in inflamed areas[33]; inhibition of DC activation[34]; antagonism of NF-κB, which leads to decreased IL-1β and TNF production; and induction of the inflammation-modulating cytokine TGF-β.

## Summary

Dietary components can have a variety of effects on the inflammatory process and on bone destructive pathways (Table 68-2). Thus alterations in diet may have effects on both the risk and management of rheumatic diseases, as is discussed later in this chapter.

**TABLE 68-2** Effects of Dietary Components on Inflammatory and Bone Destructive Pathways

| |
|---|
| **n-3 Fatty Acids** |
| Decreased production of n-6–derived eicosanoids ($PGE_2$, $TXA_2$, $LTB_4$), which have pro-inflammatory effects |
| Increased production of n-3–derived eicosanoids ($PGE_3$, $TXA_3$, $LTB_5$), which in general are less pro-inflammatory |
| Decreased IL-1β and TNF production |
| Increased production of specialized proresolving lipid mediators (resolvins, protectins, maresins, lipoxins) |
| Decreased major histocompatibility complex II expression by antigen-presenting cells |
| Decreased adhesion molecule expression: ICAM, VCAM, LFA |
| Decreased expression of matrix metalloproteinases |
| Alteration in RANK/OPG ratio |
| **Vitamin D** |
| Inhibition of monocyte differentiation into DCs and promotion of DC apoptosis |
| Induction of tolerogenic Tregs with enhanced suppressive activity |
| Inhibition of monocyte/macrophage IL-1β and TNF production |
| Inhibition of Th1 cell proliferation and cytokine production |
| Enhancement of Th2 cytokine production |
| Reduction in Th17 cell differentiation and IL-17A production |
| Inhibition of proliferation of activated B cells, differentiation of activated B cells and immunoglobulin secretion |
| **Antioxidants** |
| Scavenge reactive oxygen species |
| Reduce pro-inflammatory eicosanoids, TNF, and IL-1β |
| **Probiotics** |
| Generation of $CD4^+$ Tregs in inflamed areas |
| Inhibition of DC activation |
| Decreased IL-1β and TNF production via inhibition of nuclear factor-κB |
| Increased production of transforming growth factor-β |

DC, Dendritic cell; ICAM, intercellular adhesion molecule; IL, interleukin; LFA, leukocyte function-associated antigen; LTB, leukotriene B; PGE, prostaglandin E; RANK/OPG, receptor activator of nuclear factor-κB/osteoprotegerin; Th, T helper; TNF, tumor necrosis factor; TXA, thromboxane A; VCAM , vascular cell adhesion molecule.

# NUTRITION IN THE ETIOLOGY OF RHEUMATIC DISEASES

## Rheumatoid Arthritis

**KEY POINTS**

- **Assessment of dietary intake is difficult, and identification of a single dietary factor that regulates disease might not be possible.**
- **Omega-3 fatty acids may protect against RA.**
- **The association between vitamin D and RA remains unclear.**
- **Obesity might affect disease activity and outcomes in RA.**

A number of epidemiologic studies have examined the role of nutrition in the etiology of RA. Assessment of dietary intake in epidemiologic studies is difficult, and to identify the effects of a single dietary variable and distinguish it from other nutritional and lifestyle factors may not be possible. Notwithstanding, a number of nutritional factors are candidates for an influence on the development of RA.

### Omega-3 Fatty Acid Consumption

The long-chain n-3 fats, EPA and DHA are most abundant in fish and fish oils. A protective effect against RA of fish intake has been reported. For example, the Seattle Women's Health Study showed reduced risk for RA in participants who consumed two or more fish meals per week with an adjusted odds ratio (OR) of 0.57 (95% confidence interval [CI], 0.35 to 0.93) compared with participants who consumed less than one fish meal per week.[35] Another population-based, case-controlled study reported a modest decrease in the risk of RA in subjects who consume oily fish one to seven times per week compared with those who seldom or never consumed fish (OR, 0.8; 95% CI, 0.6 to 1).[36] A subsequent long-term cohort study found that sustained consumption of fish was associated with reduced risk for RA (relative risk [RR], 0.48;95% CI, 0.33 to 0.71).[37]

### Red Meat and Protein Consumption

High consumption of red meat has been associated with an increased risk of inflammatory polyarthritis (OR, 1.9; 95% CI, 0.9 to 4.0).[38] Although one study reported that meat and offal were associated with an increased risk for RA,[39] this was not confirmed in other studies.[40,41] Whether the association between red meat consumption and inflammatory arthritis is causative remains unclear, although the presence of significant amounts of AA in red meat may provide some explanation for the association.

### Tea and Coffee Consumption

Tea and coffee have been identified as potential risk factors for RA. In the Finnish National Health Study, consumption of four or more cups of coffee per day was associated with an increased risk of rheumatoid factor (RF)-positive RA, but not RF-negative RA, after adjustment for potential confounders such as age, smoking, and gender (RR, 2.2; 95% CI, 1.13 to 4.27).[42] The Iowa Women's Health Study found no association between daily caffeine intake and risk for RA. However, women who consumed four or more cups of decaffeinated coffee per day were at increased risk for RA compared with non–coffee drinkers (RR, 2.58; 95% CI, 1.63 to 4.06). Furthermore, women who consumed three or more cups of tea per day had a reduced risk of RA (RR, 0.39; 95% CI, 0.16 to 0.97).[43] More recent studies have not shown an association between tea/coffee and RA.[40,44] A recent meta-analysis stratified by seropositivity reported a positive association between coffee consumption and seropositive RA (RR, 1.34; 95% CI, 1.16 to 1.52) but not seronegative RA (RR, 1.09; 95% CI, 0.88 to 1.35). No association was found between tea consumption and RA.[45]

Although the epidemiologic evidence for an association between coffee/tea and RA is equivocal, interest has been sustained by the presence of metabolically active agents within these beverages. For example, the major catechin in tea inhibits induction of inducible nitric oxide synthase (iNOS) by stimulated macrophages.[46] iNOS generates highly reactive free radical products while di-imidating substrate arginine moieties to citrulline. Citrullinated peptides/proteins are recognized immunogens that provide a focus for autoimmunity in RA. Green tea extract has been shown to increase chemokine receptor expression and reduce chemokine production in RA synovial fibroblasts.[47] Gallic acid, a natural polyphenolic acid found in tea, has been reported to induce apoptosis of RA fibroblast-like synoviocytes (FLS) and to reduce the expression of IL-1 and IL-6 genes in RA FLS.[48]

### Alcohol Consumption

Alcohol consumption may reduce the risk for RA. In a case-control study of 515 patients with RA, alcohol consumption was associated with a reduced risk of anti-citrullinated protein antibody (ACPA)-positive RA.[49] A dose-dependent inverse relationship between alcohol consumption and risk of RA was also demonstrated in two independent case-control studies (the Swedish Epidemiologic Investigation of Rheumatoid Arthritis [EIRA] and the Danish case-control study of rheumatoid arthritis [CACORA] studies).[50] The reduction in risk of RA was more pronounced in patients with the shared epitope compared with those without the shared epitope and most pronounced in smokers with the shared epitope.[50] In the most recent study, with use of data from the Nurses Health Studies I and II involving 1.90 million years of person-time from 1980 to 2008, there was a modest reduction in the risk of RA with long-term moderate alcohol use. The adjusted hazard ratio (HR) for alcohol use of 5 to 9.9 g/day was 0.78 (95% CI, 0.61 to 1.00), with a stronger association observed in those with seropositive disease (HR, 0.69; 95% CI, 0.50 to 0.95).[51]

With regard to candidate mechanisms for this putative reduction in risk for RA, alcohol has been shown to downregulate the production of pro-inflammatory cytokines and upregulate production of the anti-inflammatory cytokine IL-10.[52,53] Furthermore, in a murine model of arthritis, ethanol almost totally prevented the development of collagen-induced arthritis, and in those mice that did develop arthritis, the disease was less severe. These anti-inflammatory effects of ethanol were associated with reduced leukocyte migration, downregulation of NF-κB, and reduced production of the pro-inflammatory cytokines IL-6 and TNF, but not the anti-inflammatory cytokine IL-10.[54]

### Sugar-Sweetened Beverages

Sugar-sweetened beverage consumption has been associated with gout and other inflammatory diseases, including diabetes. In the Nurses' Health Study I and II, women who consume one or more sugar-sweetened beverage per day have an increased risk for seropositive RA (HR, 1.63; 95% CI, 1.15 to 2.30) compared with women who consume no or less than one serving per month. This effect remained significant after adjustment for BMI. No association between sugar-sweetened beverage consumption and seronegative

RA was observed.[55] Sucrose consumption has been implicated in the development of periodontal infection, which has been linked to the development of RA. Soda drinks, which contain high-fructose corn syrup and sucrose, have been associated with higher CRP, IL-6, and TNF receptor-2 concentrations in patients at risk of cardiovascular disease (CVD).[56] However, the exact mechanisms linking sugar-sweetened beverages and RA remain to be determined.

### Vitamin D

As noted earlier, vitamin D has anti-inflammatory actions. Although vitamin D has been implicated in reducing the risk of the autoimmune diseases, diabetes,[57] and multiple sclerosis, its association with the risk of RA is less clear.[58]

The Iowa Women's Health Study reported that a higher intake of vitamin D was associated with a reduced risk of RA (RR, 0.67; 95% CI, 0.44 to 1.00, $P = 0.05$) in women aged 55 to 69 years.[59] However, in a large study of 186,389 women followed up for 22 years, no association was found between dietary intake of vitamin D and the risk of developing RA.[60] Apart from supplements, the main source of vitamin D is de novo synthesis in the skin, thus estimated dietary intake may be a poor predictor of serum vitamin D concentrations. In a study of 79 patients with RA, no association was found between prior serum vitamin D concentrations and subsequent development of RA.[61] However, it is notable that the geometric means for both patients and controls in this study were only half the lower reference level of 60 nmol/L, which has been set subsequently to reflect a level that suppresses secondary hyperparathyroidism resulting from vitamin D insufficiency. A recent meta-analysis revealed a reduced risk of RA with higher vitamin D intake (RR of highest vs. lowest intake groups, 0.76; 95% CI, 0.58 to 0.94).[62] Randomized controlled trials of sufficient size and duration are required to determine whether the observed relationship between vitamin D and RA is causal and to establish the most effective dose, duration, and serum vitamin concentration to prevent RA.

### Antioxidants and Risk of Rheumatoid Arthritis

Oxygen free radicals (e.g., nitric oxide, superoxide, and hydroxyl radical) are implicated in the tissue damage observed in RA.[63] Antioxidants, including vitamin E (α-tocopherol), vitamin C (ascorbic acid), β-carotene, and selenium, may have a protective role against tissue damage caused by oxygen free radicals. This fact, combined with evidence that markers of antioxidant nutritional status are lower in patients with established RA compared with healthy controls,[64] led to the hypothesis that antioxidants may protect against the development of RA. Despite this biologic plausibility, the available data do not provide clear evidence for a protective effect of antioxidants as dietary supplements in relation to the development of RA.

Low serum concentrations of vitamin E, β-carotene, retinol, and selenium have been reported to be weakly associated with an increased risk for RA in some, but not all, studies.[65-67] The strongest association between risk of RA and antioxidants was found for a combined antioxidant index, rather than for any specific antioxidant.[65]

High dietary intake of β-cryptoxanthin (a carotenoid found in fruit and vegetables) and zinc may protect against the development of RA.[68,69] Low vitamin C intake has been associated with an increased risk of inflammatory polyarthritis with an adjusted OR of 3.3 (95% CI, 1.4 to 7.9) for the lowest tertile of vitamin C intake (<55.7 mg/day) compared with the highest intake tertile (>94.9 mg/day).[70] However, another study found no association between intake of vitamin C, vitamin E, zinc, or selenium and the development of RA.[40]

The Women's Health Study, a randomized, double-blind, placebo-controlled trial designed to evaluate the effects of low-dose aspirin and vitamin E in the primary prevention of cardiovascular disease and cancer, has been used to address the influence of vitamin E supplementation (600 IU on alternate days) on the development of RA. During the 10-year follow-up period, 106 cases of RA occurred with no significant association between vitamin E supplementation and incidence of cases of RA. A statistically insignificant trend toward inverse association between vitamin E and development of seropositive RA was seen on subgroup analysis.[71]

### Obesity and Rheumatoid Arthritis

Studies that examined the association between obesity and the risk of RA have had conflicting results, with findings of both increased risk of RA[72,73,74] and no association between the two.[75,76] The most recent study, a prospective cohort study that followed more than 200,000 women during a 30-year period, reported an increased risk of RA associated with high BMI in patients diagnosed with RA before age 55 years. Furthermore, if women were obese at age 18 years, they had a 35% increased risk for RA, which reached an almost 50% increased risk with regard to seropositive RA.[74]

The association between obesity and a pro-inflammatory state provides a rational link between disease activity and severity in RA. Higher BMI has been associated with less radiographic damage.[77-80] Increased plasma concentrations of the adipokines, leptin, adiponectin, and visfatin have been observed in patients with RA compared with healthy controls.[81] Visfatin and leptin have been associated with increased and reduced radiographic joint damage, respectively,[80] although more recent data suggest that adipokines do not mediate the observed association between BMI and radiographic damage.[78] Although radiographic damage may be less in patients with higher BMI, other indicators of disease severity and comorbidities are adversely affected. For example, higher BMI (≥30 kg/m$^2$) has been associated with higher disease activity, Health Assessment Questionnaire (HAQ) scores, pain scores, and requirement for joint replacements.[82] Higher BMI is also associated with less chance of achieving disease remission or low disease activity.[82,83] Obese patients with RA are also at increased risk for important comorbidities, including hypertension, diabetes, and ischemic heart disease.[82,84] The cause of the apparent disconnect between obesity and disease severity and radiographic damage remains unclear, but one potential explanation is altered body composition in RA, which may create an inaccurate BMI measurement.

The body can be divided into fat mass and fat-free mass (consisting of body cell mass and connective tissue).

Rheumatoid arthritis commonly leads to changes in body composition, with fat-free mass reported to be 13% to 14% lower in patients with RA.[85] This loss of fat-free mass is often associated with increased fat mass with unchanged body weight, a state known as *rheumatoid cachectic obesity*. Approximately one in five RA patients may have rheumatoid cachexia, as defined by fat-free mass index lower than the 25th percentile, and fat mass index higher than the 50th percentile of a reference population.[86] BMI, the commonly used measure of obesity, does not distinguish between fat mass and fat-free mass, thus individuals of similar height and weight, but different body composition, will have a similar BMI. Patients with RA have been shown to have higher body fat and BMI than healthy controls. However, for a given mass of body fat, BMI was lower in patients with RA compared with healthy controls.[87] On the basis of this, the authors suggest that the categories of BMI should be adjusted downward in patients with RA.

## Gout

| KEY POINTS |
|---|
| The link between diet and gout has been recognized for centuries. |
| High intake of meat, seafood, and alcohol is associated with increased risk of gout. |
| Dietary fructose increases serum urate. |
| Higher intake of low-fat dairy products has been associated with a reduced risk of gout. |
| Increased BMI predisposes to gout. |

For centuries gout has been associated with overindulgence in rich food and wine. Gout occurs when serum urate (SU) concentrations reach super saturation concentrations (~6.8 mg/dL at 37° C), resulting in the formation of monosodium urate crystals, which deposit in joints and soft tissues. Urate is the end product in the breakdown of purines, which are a product of cellular turnover or are ingested in the diet. The purines adenosine and guanine are present in nucleic acids and the intra-cellular energy transporters adenosine triphosphate and guanosine triphosphate. Accordingly, foods derived from metabolically active animal tissues may increase dietary purine load.

### Dietary Factors and Gout

Several large clinical studies have identified an association between high intake of meat and seafood (but not total protein intake) and both SU concentrations[88] and gout.[89] In comparison, the risk of gout is reduced with higher intake of low-fat dairy products and long-term coffee consumption.[89,90] More recently, fructose, which is found in corn syrup, sugar-sweetened soft drinks, and fruit juices, has been associated with hyperuricemia and gout.[91,92] Fructose increases SU through increased purine degradation.[93] Furthermore, urate and fructose share a common transporter within the kidney (*SLC2A9*).[94] Recent data shows a gene environment interaction between fructose and the renal urate transporter *SLC2A9*[95] and variations in *SLC2A9* influence the serum urate response to a fructose load.[96] Alcohol consumption other than moderate wine intake is associated with an increased risk of gout, with beer conferring a higher risk than liquor.[97]

Dietary vitamin C supplementation has been shown to reduce the risk of gout (RR of gout with no supplementation vs. 1000 to 1499 mg vitamin C/day, 0.66 [95% CI, 0.49 to 0.88]).[98] Vitamin C (ascorbic acid) is an important vitamin that can only be obtained through dietary intake. Because ascorbic acid is water soluble, it is not stored within the body and thus must be regularly supplemented through the diet to maintain the ascorbic acid pool. Dietary sources of ascorbic acid include fresh fruits and vegetables, in particular citrus fruits and green leafy vegetables such as broccoli.

### Fasting and Gout

Prolonged periods (2 weeks to 8 months) of fasting in obese patients result in a significant increase in SU and in some cases the development of gout.[99] In patients with previously documented gout, a 1-day fast led to an increase in SU of 0.5 to 2.1 mg/dL with a mean rise of 1.1 mg/dL, with refeeding associated with a return in SU to baseline levels after 24 hours.[100] Explanations for the increase in SU during fasting include increased urate production, decreased excretion because of decreased glomerular filtration rate, altered renal tubular transport of uric acid, and competition with ketones for renal tubular excretion.[101]

### Obesity and Gout

High BMI predisposes to gout.[102] In a study comparing obese men (mean BMI, $34 \pm 4$ kg/m$^2$) with healthy controls (BMI, $21 \pm 1$ kg/m$^2$), SU concentrations were raised to a similar degree in the obese patients (~$8.0 \pm 1.6$ mg/dL vs. controls, $5.2 \pm 0.81$ mg/dL), regardless of body fat distribution (predominantly visceral or predominantly subcutaneous). By contrast, 80% of patients with hyperuricemia and accumulation of fat subcutaneously had low 24-hour urinary urate excretion compared with 10% of their counterparts with fat accumulation predominantly in a visceral distribution. These data suggest that the mechanism of hyperuricemia may vary depending on body fat distribution.[103] In a separate study that used computed tomography to determine transverse area of abdominal fat components, visceral fat was shown to correlate strongly with SU, whereas no relationship was seen between SU and BMI or cross-sectional area of subcutaneous fat.[104]

## Osteoarthritis

| KEY POINTS |
|---|
| Obesity is associated with knee osteoarthritis (OA). |
| Direct biomechanical effects of obesity contribute to OA. |
| Increased leptin provides another link between obesity and OA. |

Associations have been established between obesity and onset and progression of knee OA. There is an almost

exponential increase in the risk of knee OA while BMI increases.[105] The evidence for an association between obesity and OA of the hip or hand is less well defined, although a meta-analysis reported a twofold increase in the risk of hand OA in obese individuals compared with those of normal weight.[106] In addition to direct biomechanical effects of obesity on the joint, there appears to be an important role for the adipokines, including leptin, adiponectin, resistin, visfatin, and chimerin.

Expression of leptin was increased in advanced OA cartilage compared with minimally damaged OA cartilage, with a correlation between the leptin mRNA expression in advanced OA cartilage and BMI. Furthermore, leptin was shown to reduce chondrocyte proliferation and increase IL-1β, MMP-9, and MMP-13 expression.[107]

Dietary antioxidants (vitamin E, vitamin C, and β-carotene) have been reported to reduce progression of knee OA but have no effect on the onset of OA.[108,109] The association between serum vitamin D concentrations and OA remains unclear. One study reports no association between vitamin D and risk of joint space narrowing or cartilage loss in knee OA,[110] but another study reports a positive association between knee cartilage volume and serum vitamin D concentrations.[111] A recent meta-analysis concluded that there was moderate evidence for an association between low levels of vitamin D and radiographic progression of knee OA and strong evidence for an inverse association between vitamin D and cartilage loss.[112]

## NUTRITION IN THE MANAGEMENT OF RHEUMATIC DISEASES

The role of nutrition in the management of gout is well accepted. However, its role in other rheumatic diseases such as RA is less routine. Despite a relative lack of interest or emphasis from physicians, many patients consider food may contribute to their arthritis and seek information about or try putative dietary remedies. A convincing, informed approach to nutritional advice is thus an important aspect of management, which can help patients avoid worthless interventions that are expensive, time consuming, in some cases harmful, and can divert patients from more effective measures (summarized in Figure 68-3). Furthermore, positive advice regarding dietary choices may empower the patient at a time when they often experience a sense of loss of control. Well-informed, authoritative dietary advice can also protect patients from poorly grounded advice from relatives, friends, and nonauthoritative Internet sites about dietary measures.

### Rheumatoid Arthritis

**KEY POINTS**

**Omega-3 fatty acids modestly reduce disease activity and NSAID requirements.**

**There is no evidence for the benefit of antioxidants in the management of RA.**

**Fasting, vegetarian/vegan, and elimination diets are difficult to sustain, and it is difficult to predict which patients may respond.**

**The vascular benefits of omega-3 fatty acids are important in RA patients because they have an increased risk of cardiovascular disease.**

**Some dietary variables may interact with methotrexate.**

#### Dietary n-3 Fatty Acids in the Management of Rheumatoid Arthritis

Fish oil is a rich source of the anti-inflammatory long-chain n-3 fatty acids EPA and DHA. The threshold dose of EPA and DHA usually required to obtain an anti-inflammatory effect is 2.7 g/day of EPA plus DHA, which is the equivalent of nine or more standard 1 g fish oil capsules or 10 mL of bottled fish oil per day. This dose is generally more than that with which patients will self-prescribe, although community awareness of required doses varies. Tissue levels of EPA and DHA from fish and fish oils are increased when dietary n-6 fatty acid intake is reduced concomitantly through substitution of n-6 rich visible fats (e.g., with a base of corn oil, soy oil, sunflower oil) with unsaturated products with less n-6 fat (with a base of olive oil, rapeseed/canola oil, or flaxseed oil).[113]

Krill oil has been promoted as a potent form of marine oil that allows an anti-inflammatory dose of omega-3 fats to be taken within a single capsule. There is no substance to these claims as there are no published trials of krill oil treatment in RA, and krill oil has less EPA plus DHA than standard fish oil (approximately 25% for krill oil vs. 30% for fish oil).[114] The EPA and DHA are present within phospholipids and as free fatty acids in krill oil and within triglycerides in fish oil.[115,116] EPA and DHA are moderately better absorbed from krill oil such that equal gravimetric doses of krill oil and fish oil supplements achieve similar blood levels of omega-3 fatty acids.[114-116] Krill oil contains astaxanthin, which gives it a reddish color and has antioxidant properties. As discussed elsewhere in this chapter, there is no evidence for important antiarthritic or anti-inflammatory effects of antioxidants. There have been no studies into the effect of astaxanthin in RA. Because krill oil is substantially more expensive than fish oil and, in contrast to fish oil, has not been subjected to systematic study of anti-inflammatory effects, krill oil is not a suitable substitute for fish oil.

In general, patients with recent-onset or more established RA can be expected to achieve better disease control when anti-inflammatory doses of fish oil are co-administered with appropriately intensive combination disease-modifying anti-rheumatic drug (DMARD) therapy. In a longitudinal cohort study of patients with recent-onset RA (<12 months' duration), response-driven, intensive combination DMARD therapy was combined with either supplemental fish oil or placebo. At 3 years, those patients compliant with fish oil therapy had improved self-reported function in activities of daily living, lower tender joint counts, lower erythrocyte sedimentation rate (ESR), higher remission rates (72% vs. 31%), and less NSAID use than those who did not consume fish oil.[117] The better outcome for patients taking fish oil is consistent with randomized controlled trial data that show reduced symptoms with fish oil compared with placebo treatment. This study also demonstrates the feasibility of long-term fish oil use, in this case

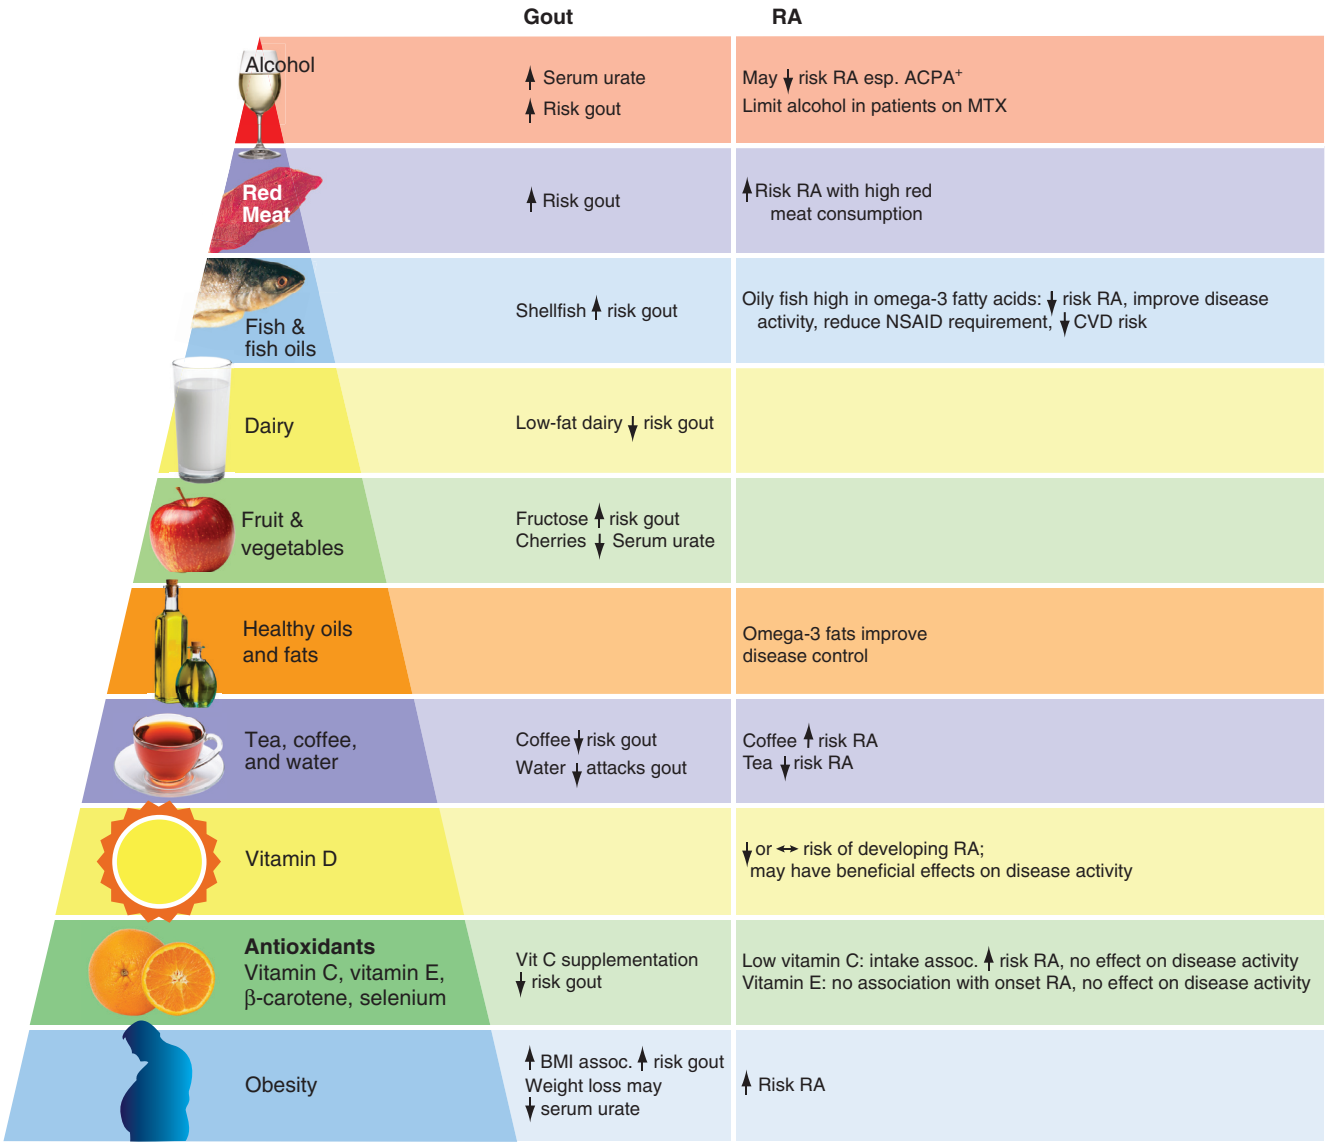

**Figure 68-3** Summary of nutrition in rheumatic diseases. ACPA, Anti-citrullinated protein antibody; BMI, body mass index; CVD, cardiovascular disease; MTX, methotrexate; NSAID, nonsteroidal anti-inflammatory drug; RA, rheumatoid arthritis; Vit, vitamin.

more than 3 years. Although fish oil usage may identify more compliant patients, overall DMARD usage was similar in the two groups. A more recent study compared high-dose fish oil to low-dose fish oil, 5.5 or 0.4 g/day, respectively, of the omega-3 fats, EPA + DHA, in DMARD naïve patients with early RA. Fish oil was used in combination with a treat-to-target predetermined intensive combination DMARD protocol. During 12 months of treatment, patients receiving high-dose fish oil were more likely to achieve ACR remission (HR, 2.17;95% CI, 1.07 to 4.42; $P = 0.03$) and triple therapy with methotrexate, sulfasalazine, and hydroxychloroquine (HR, 0.28; 95% CI, 0.12 to 0.63; $P = 0.002$) was less likely to fail.[118]

Anti-inflammatory doses of fish oil have been shown to reduce NSAID requirements in patients with RA in other studies.[119,120] NSAIDs alter the balance of $PGE_2/TXA_2$ in favor of $TXA_2$, thereby increasing the production of IL-1β and TNF by monocytes.[121] By contrast, fish oil has been shown to reduce the production of these cytokines.[14] Fish oil also lacks many of the adverse effects associated with NSAIDs (Table 68-3). The direct effects of fish oil and their influence on NSAID use may potentially reduce long-term tissue damage associated with release of these cytokines, although this remains to be established.

Important for both patients and physicians to recognize is that, as with most standard DMARDs, there is a latent period of as long as 15 weeks before the symptomatic benefits of anti-inflammatory doses of fish oil are experienced. One small pilot study has shown that this latent period can be reduced with intravenous administration of n-3 fats.[122] Although the inconvenience and cost of intravenous therapy is a barrier to this approach, the benefits of short-term intravenous therapy can be prolonged by a switch to oral n-3 supplementation.[123]

**TABLE 68-3** Comparison between Nonsteroidal Anti-inflammatory Drugs and Anti-inflammatory Doses of Fish Oil

| | NSAIDs | Fish Oil |
|---|---|---|
| COX inhibition | COX-1/COX-2 selectivity varies depending on agents | Nonselective |
| NSAID sparing | No | Yes (↓ prostaglandin $E_2$) |
| Serious cardiovascular events | Increased risk for MI | Reduced cardiac mortality |
| Blood pressure | Increased | Reduced |
| TNF and IL-1β | Increased | Reduced |
| Upper gastrointestinal bleeding | Increased | Not reported |
| Time to effect | Rapid | Delayed (≤3 mo) |

COX, Cyclooxygenase; IL-1β, interleukin-1β; MI, myocardial infarction; NSAID, nonsteroidal anti-inflammatory drug; TNF, tumor necrosis factor.

**Adverse Effects of Fish Oils.** The most common adverse effects associated with fish oil in anti-inflammatory doses are a fishy aftertaste, gastrointestinal upset, and nausea. These side effects are clearly neither organ nor life threatening, but they can be dose limiting. Patient preferences vary, but in general, bottled fish oil layered on juice is the most efficient way to take an anti-inflammatory dose (one quick swallow compared with 10 to 15 standard fish oil capsules). Fish oil is best tolerated with food and not on an empty stomach. In general, fish oil is best tolerated when take just before the evening meal or other main meal of the day. The term *fish oil* defines oil prepared from fish bodies to provide a distinction from cod liver oil, which is prepared from fish livers and is rich in the fat-soluble vitamins A and D. Standard fish oil contains more EPA plus DHA (30% w/w) than cod liver oil (EPA plus DHA ~20%) and is the preferred material. Vitamin D can be given separately as needed, and vitamin A supplementation is best avoided because negative effects on bone mineral density and fracture risk have been reported.[124]

Although anti-inflammatory doses of fish oil have not been associated with serious toxicity, concerns may be raised. One consideration is a putative bleeding tendency associated with therapeutic fish oil ingestion. This notion has its origins in studies of Greenland Eskimos consuming their aboriginal diet, in whom myocardial infarction is rare and bleeding times were prolonged relative to those observed in Danes.[125] However, these concerns need to be placed within the context of the high amounts of EPA and DHA in the aboriginal Eskimo diet (more than double the threshold anti-inflammatory dose) and the lower amounts of antagonistic n-6 fatty acids compared with Western diets. Although bleeding episodes have not been a feature of long-term fish oil therapy for RA,[117] and platelet EPA is fourfold lower than found in the Eskimos, surgeons may ask that fish oil be discontinued before elective surgery. Also, pharmacists may advise patients to discontinue fish oil while taking warfarin, even though no increase in bleeding tendency has been seen in patients undergoing cardiac surgery when taking fish oil concomitantly with warfarin, aspirin, or aspirin plus clopidogrel therapy.[126,127] More recent clinical trials also suggest that higher doses of fish oil can be taken for prolonged periods without increased bleeding events or other serious adverse effects.[118,128]

Two recent studies have shown an apparent protective effect of low plasma phospholipid DHA against prostate cancer.[129,130] However, the warning of the authors regarding therapeutic use of fish oil is problematic for several reasons. Neither study was designed to examine the effects of fish oil supplementation on prostate cancer risk, and the observed levels of DHA were low and in the range that is only weakly associated with dietary intake. Furthermore, the influence of intake of red meat and animal fat, which have been associated with increased risk for prostate cancer and are an important dietary sources of EPA and DHA in those who infrequently or rarely eat fish, was not considered as a potential confounder.[131]

Another concern is the possible presence of the environmental contaminants methylmercury, polychlorinated biphenyls (PCBs), and dioxins, which are concentrated in large carnivorous fish. These toxins are excluded from properly prepared fish oil for therapeutic use. The U.S. Food and Drug Administration has accorded "generally regarded as safe" status to intakes of as much as 3 g/day of long-chain n-3 fatty acids from marine sources.

**Role of Omega-3 Supplementation in Rheumatic Diseases with Increased Cardiovascular Disease Risk.** A number of rheumatic diseases, including RA, SLE, gout, and psoriatic arthritis are associated with increased cardiovascular mortality. n-3 Fatty acids have the potential to alter cardiovascular risk through multiple mechanisms, including stabilization of the myocardium, leading to reduction in cardiac arrhythmias, reduced blood pressure, stabilization of atheromatous plaques, reduced triglycerides and increased high-density lipoprotein (HDL), decreased platelet thromboxane release, increased vascular prostacyclin release, and anti-inflammatory effects (Figure 68-4). A recent meta-analysis of trials of n-3 and n-6 fatty acid supplements at various doses and with various cardiac endpoints reported no reduction in overall cardiac events, although a significant association between plasma long-chain n-3 PUFA levels and reduced cardiac events was found.[132] A meta-analysis of randomized trials of omega-3 supplements and particular cardiovascular outcomes showed a modest but significant reduction in cardiac death.[133] The effect size appeared to have reduced in more recent studies, possibly as a result of more intensive management of tractable cardiovascular risk factors.

To date there have been no specific studies of the cardiovascular benefits of n-3 fatty acid supplementation in patients with RA or other rheumatic diseases. However, patients with early RA receiving fish oil have been shown to have lower triglycerides, increased "good" HDL cholesterol, less NSAID use, greater disease suppression, and reduced platelet synthesis of $TXA_2$, all of which can be expected to reduce cardiovascular risk.[117] The blood levels of patients taking EPA plus DHA achieved with anti-inflammatory doses of fish oil[117] are above the threshold associated with reduced risk for sudden cardiac death.[134]

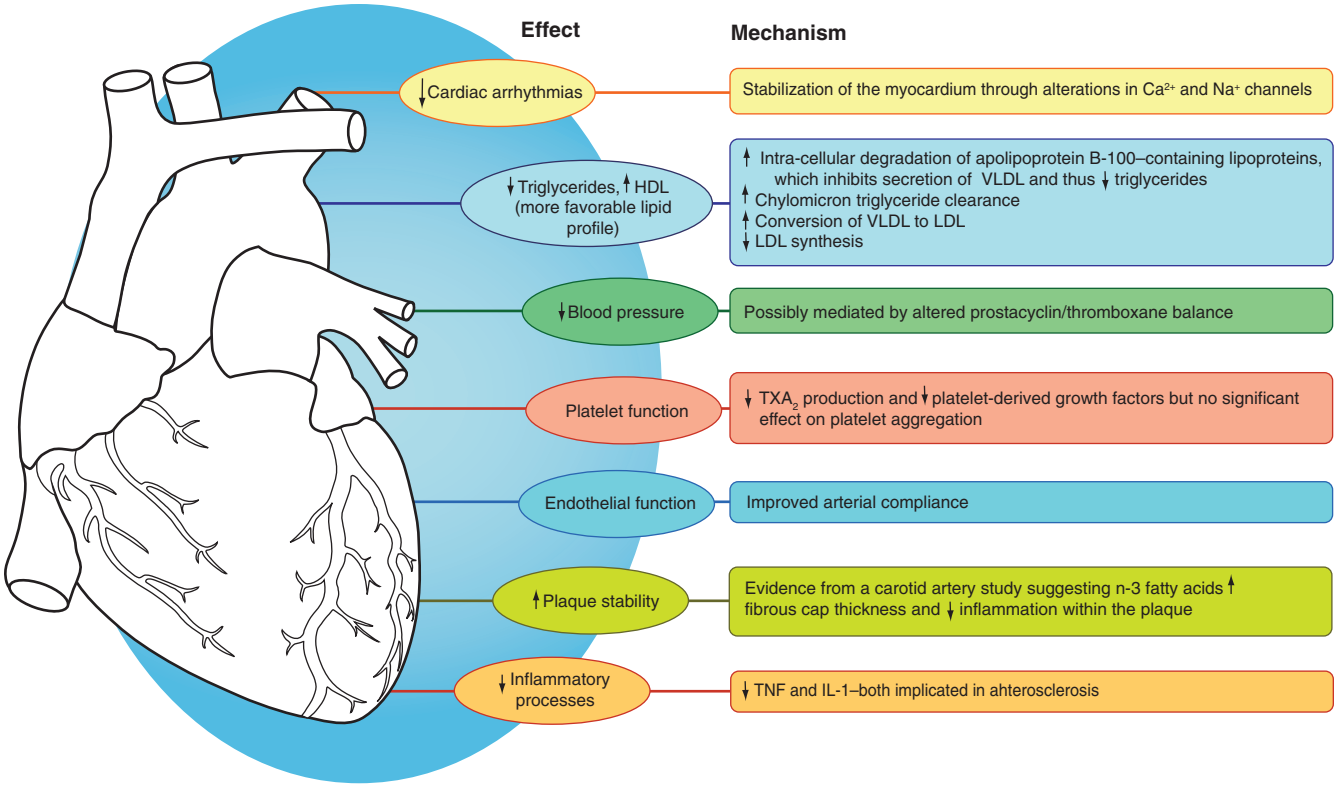

**Figure 68-4** Effects of omega-3 fatty acids on the cardiovascular system. HDL, High-density lipoprotein; IL, interleukin; LDL, low-density lipoprotein; TNF, tumor necrosis factor; $TXA_2$, thromboxane $A_2$; VLDL, very-low-density lipoprotein.

## Antioxidants in the Management of Rheumatoid Arthritis

Despite the association between ROS and RA, a recent meta-analysis shows no convincing evidence that antioxidant supplementation improves disease control in patients with RA.[135]

**Vitamin E.** Serum concentrations of vitamin E are similar in patients with RA and healthy controls.[136] In rats with CIA fed 200 mg/kg of vitamin E for 4 weeks, a significant reduction in leptin, TNF, and IL-6 concentrations was seen compared with control-fed mice.[137] A 12-week placebo-controlled study of vitamin E supplementation in patients with RA showed a reduction in pain scores but no effect on joint tenderness score, duration of morning stiffness, swollen joint count, or laboratory parameters.[138]

**Vitamin C.** Although animal models have shown benefits with vitamin C supplementation, human studies have not shown any clinical benefit in patients with RA.[139]

**Selenium.** Although not an antioxidant per se, selenium is found at the active site of the enzyme glutathione peroxidase, an important antioxidant enzyme. Plasma concentrations of selenium are reduced in patients with RA compared with healthy controls,[140] and an inverse association between serum selenium concentrations and active joints has been reported.[141] Notwithstanding, studies of selenium supplementation have not shown clinical benefit in patients with RA, despite increases in serum and red blood cell selenium concentrations.[142,143] However, polymorphonuclear cell selenium concentrations do not increase with dietary supplementation, which may explain the lack of clinical effect.[144]

## Vitamin D and the Management of Rheumatoid Arthritis

Animal models have shown that $1,25(OH)_2D$ can prevent and have therapeutic benefits in experimental arthritis.[145] Studies examining the relationship between serum vitamin D concentrations and disease activity in RA have been conflicting: Both an inverse relationship[146,147] and no relationship[148] have been observed. However, increases in patient global visual analogue scores seen in patients with lower serum vitamin D may confound results of the disease activity scale (DAS)28.[149]

In humans, the vitamin D receptor has been shown to be expressed at sites of cartilage erosion and in chondrocytes and synoviocytes in patients with RA but not healthy control subjects, suggesting that vitamin D may have local effects within the inflamed joint.[150] Supplemental vitamin D is usually prescribed to patients with RA for treatment or prophylaxis of osteoporosis. However, a 12-month trial of vitamin D (calciferol) 100,000 IU/day showed improvement in RA disease activity and a reduction in the requirement for analgesics and NSAIDs.[151] In another small study of 19 patients with RA, oral α-calcitriol 2 μg/day was observed to have a beneficial effect on disease activity compared with placebo.[152] Neither significant side effects nor increases in serum calcium were reported in either of these studies. Vitamin D has been reported to induce TNF production, suggesting that it may alter responses to TNF inhibitor therapy in RA. A recent study showed that $1,25(OH)_2D_3$, but not TNF blockade, suppressed IL-17A and IL-22 production in co-cultures of Th17 cells and RA synovial fibroblasts from patients with early RA.

Furthermore, the combination of $1,25(OH)_2D_3$ and TNF blockade resulted in a significant additive effect with reductions in IL-6, IL-8, MMP-1, and MMP-3.[153] These data suggest there may be a rationale for patients receiving TNF inhibitor therapy to receive supplemental vitamin D.

It is important to recognize that cod liver oil, a rich source of dietary n-3 fatty acids, is also rich in vitamin D. Cod liver oil has been used in the management of RA in sufficient doses to deliver anti-inflammatory doses of long-chain n-3 fatty acids.[154] Although serum vitamin D concentrations rose significantly, the study did not allow for the respective contributions of vitamin D and co-ingested n-3 fatty acids to be evaluated. The relatively high content of vitamin A in cod liver oil militates against its use for delivering anti-inflammatory doses of n-3 fatty acids.

### Dietary Restriction in Rheumatoid Arthritis—Fasting, Vegetarian, and Elimination Diets

A number of studies have examined elimination of different nutrients from the diet in the management of RA. At the extreme, total fasting and subtotal fasting reduced clinical and laboratory parameters of disease activity in some patients within a few days, but deterioration occurred on reintroduction of food.[155] Thus fasting is an impractical management strategy because it should last no longer than 7 days and the positive effects are short-lived, whereas RA is a chronic disease. A number of potential mechanisms for this improvement have been postulated, including a psychological or placebo effect, weight loss, and immunosuppression as a result of reduced caloric intake, alteration in fatty acids and IL-6 concentrations, and alterations in gut flora.

Elemental diets are used with the aim of providing major food groups as simpler components (e.g., protein as free amino acids, fat as medium-chain triglycerides, carbohydrates as small sugars). Minimal general benefit was seen in only a minority of patients, with a lack of benefit observed in objective parameters such as inflammatory markers, and swollen and tender joint counts.[156,157]

Vegetarian and vegan diets have also been studied in RA. Response to these diets has been variable, with poor patient compliance and high dropout rates resulting from both lack of efficacy and adverse effects (mainly nausea and vomiting).[158,159] More recently, a meta-analysis of four clinical trials of fasting, followed by vegetarian diets that lasted at least 3 months, showed that clinically significant long-term benefits in RA can occur.[160] However, the diet required is strict, and no means currently exist to predict which patients will respond.

Elimination diets involve avoidance of foods that are putatively allergenic. Foods are deemed to be "allergenic" if their elimination results in decreased disease activity and subsequent ingestion results in increased disease activity. Although such diets may result in improvement in a proportion of patients, variable responsiveness and compliance can be a significant limitation.[161,162] A systematic review of dietary studies in patients with RA highlighted the uncertainty of response, high risk of bias in existing studies, and the not insignificant risk of adverse effects.[163] Notwithstanding, from a practical perspective, if a patient believes their arthritis is caused by hypersensitivity to a particular food item or group, it may be worth assessing the effects of dietary avoidance in an $n = 1$ study of sequential withdrawal and challenge. Objective clinical and laboratory signs of disease activity should be documented after one or more cycles of withdrawal and reintroduction of the suspected food item. The findings can then be used as a basis to decide whether the food item should be avoided by the individual in the longer term.

### Interactions between Diet, Obesity, and Disease-Modifying Anti-rheumatic Drugs

It is well recognized that certain dietary components may interact with DMARDs. Methotrexate remains the anchor drug in the management of RA and is also used commonly in many other rheumatic diseases. Alcohol may increase the risk of hepatotoxicity in patients receiving methotrexate, and alcohol intake should be moderate at most. Methotrexate has multiple potential actions, many of which can be traced to its action as a dihydrofolate reductase inhibitor. Routine supplementation with folic acid is recommended to reduce potential adverse effects associated with methotrexate.[164] However, higher red blood cell folate concentrations have been associated with higher disease activity in patients with RA receiving methotrexate.[165] In some countries fortification of flour, pasta, rice, and bread with folic acid is a governmental requirement. Not surprisingly, such dietary fortification may lead to increased methotrexate doses in some patients.[166]

Methotrexate treatment increases extra-cellular accumulation of adenosine, which has multiple anti-inflammatory effects on neutrophils and macrophages, including inhibition of IL-1β and TNF synthesis. Caffeine is a methylxanthine and acts as an adenosine receptor antagonist. Caffeine may therefore interfere with the effects of methotrexate. In rats with adjuvant arthritis, caffeine reverses the anti-inflammatory effects of methotrexate.[167] In patients with RA, less intense caffeine intakes have been shown to have no effect on methotrexate efficacy.[168] In patients treated with methotrexate 7.5 mg per week, without folate, responses were reduced in those consuming caffeine in doses greater than 180 mg/day compared with doses less than 120 mg/day.[169]

Obesity may also have an impact on response to therapy. Several studies have reported an association between high BMI (≥25 $kg/m^2$) and poor response to therapy, particularly infliximab in patients with RA.[83,170-172]

## Gout

**KEY POINTS**

- **Dietary interventions in gout should address the association between gout and the metabolic syndrome and increased cardiovascular disease.**
- **Dehydration is a trigger for acute gout.**
- **Weight loss may reduce serum urate.**

Sustained reduction of SU to less than 6 mg/dL, or less than 5mg/dL if tophi are present, is critical for the effective management of gout. This is generally achieved through a

combination of urate-lowering therapy and dietary/lifestyle modifications. Dietary intervention on its own is insufficient to achieve target serum urate concentrations. When considering dietary interventions in the management of gout, it is important to recognize that gout is associated with the metabolic syndrome and with an increased risk of cardiovascular disease and mortality. It is important to note that there are no randomized controlled trials to support dietary and lifestyle interventions in gout.

The diet usually advocated for gout entails restricted intake of foods and drinks that contain higher amounts of purines or that are thought to precipitate acute attacks of gout. Restricted items include meat, seafood, beer/wine, and legumes. Such diets are frequently high in saturated fats and carbohydrates, which may add to the risk of metabolic syndrome.

Dehydration is a potential trigger for acute gout attacks, and increased water intake has been associated with a reduced risk of gouty attacks.[173] In a small short-term study in healthy volunteers, ingestion of cherries reduced serum urate (before urate, 3.6 ± 0.2 mg/dL vs. after urate, 3.1 ± 0.25 mg/dL; $P$ <0.05) and increased urinary urate excretion.[174] It has been suggested that cherries may prevent gout flares. In a study of 633 individuals, cherry intake during a 2-day period was associated with a 35% lower risk of gout attacks compared with no cherry intake (OR, 0.65; 95% CI, 0.5 to 0.85). A similar association was observed with cherry extract. Furthermore, when cherry intake was combined with allopurinol treatment, the risk of gout was 75% lower than during periods without either (OR, 0.25; 95% CI, 0.15 to 0.42).[175] In another small retrospective study of 24 patients with crystal proven gout consuming one tablespoon of tart cherry juice for greater than or equal to 4 months, there was a significant reduction in gout flares from 6.85 ± 1.34 flares/year to 2.0 ± 0.6 flares/year ($P$ = 0.0086).[176] The exact mechanism of action of cherries in reducing gout flares remains unclear and is likely multifactorial. Cherry products contain high levels of anthocyanins that have a number of anti-inflammatory and antioxidant effects, including inhibition of cyclooxygenase and scavenging of nitric oxide radicals.[177-179] Cherry juice has also been shown to inhibit production of IL-1β by human monocytes ex vivo by approximately 60%.[176]

Vitamin C supplementation may reduce SU concentrations.[180,181] In a study of 184 patients without gout randomly assigned to receive to placebo or vitamin C 500 mg/day for 2 months, SU was reduced significantly in the vitamin C group, with a mean reduction of –0.5 mg/dL (95% CI, –0.5 to 0.02 mg/dL) compared with the placebo group ($P$ <0.0001).[182] In the subgroup of 21 patients with baseline SU greater than 7 mg/dL, the mean reduction in serum urate was 1.3 mg/dL. However, in a small study of patients with gout, vitamin C, 500 mg/day for 8 weeks had no clinically significant urate-lowering effect alone or in combination with allopurinol.[183] Whether a larger dose of vitamin C has a more potent urate-lowering effect in patients with gout remains to be determined.

In obese patients, weight loss may reduce SU[184,185] and provide other health benefits. In one study, 13 males with gout lost weight during a 16-week period (prestudy BMI, 30.5 ± 8.1 kg/m$^2$; poststudy BMI, 27.8 ± 7.9 kg/m$^2$). SU decreased in all participants; baseline SU, 9.6 ± 1.7 mg/dL, falling to 7.9 ± 1.5 mg/dL; $P$ = 0.001. A decrease in frequency of gouty attacks was seen from 2.1 ± 0.8 attacks/month to 0.6 ± 0.7 attacks/month ($P$ = 0.002).[186] In a study of patients with type 2 diabetes, bariatric surgery, which resulted in marked weight loss, was associated with a significant reduction in serum urate. Furthermore, in the subgroup of patients with gout, serum urate was below the treatment target of 0.36 mmol/L at 12 months despite cessation of urate-lowering therapy.[187] However, not all studies have shown a reduction in SU with weight loss.[188]

There are currently no data on whether n-3 fatty acid supplementation has a role in the management of gout. However, given the effects of n-3 fatty acids on the inflammasome, they may be useful in the management of acute gout or, potentially, as prophylaxis against acute gout in conjunction with urate lowering therapy. Further clinical studies in these situations are required. Gout is often associated with hypertriglyceridemia, upon which anti-inflammatory doses of fish oil can be expected to have an ameliorating effect.[117,189]

## Osteoarthritis

**KEY POINTS**

**Weight loss is important in the management of OA.**

**From a mechanistic viewpoint, n-3 fatty acids may be beneficial and can be an alternative or adjunct to NSAIDs for long-term analgesia.**

Weight loss is generally considered an important aspect of the management of OA of weight-bearing joints. A meta-analysis of weight loss studies in patients with knee OA reported that moderate weight loss (≥5%) is associated with statistically significant improvement in self-reported disability scores. Although knee pain was also reduced, this did not reach statistical significance.[190] In a study of 44 patients with knee OA, a mean weight loss of 20% 6 months after bariatric surgery was associated with a significant improvement in pain and Western Ontario and McMaster osteoarthritis index (WOMAC) scores. Furthermore, a significant reduction in serum IL-6 and CRP was found, with a significant increase in the N-terminal propeptide of type IIA collagen, a biomarker of cartilage synthesis.[191]

Degradation and loss of articular cartilage and synovial inflammation are all characteristic features of OA. MMPs have an important role in cartilage degradation, and n-3 fatty acids have been shown to reduce IL-1α–induced expression of MMP-3 and MMP-13 in bovine chondrocyte cultures.[12] The anti-inflammatory effects of n-3 fatty acids, as compared with n-6 fatty acids discussed previously, may reduce synovial inflammation.

A high-fat diet rich in n-3 fatty acids has been shown to mitigate the effects of obesity on injury-induced OA in mice and to accelerate wound repair. By contrast, a high-fat diet rich in n-6 fatty acids was found to increase the severity of the OA.[192] OA-prone guinea pigs fed on a n-3 fatty acid–rich diet had amelioration of OA of a severity similar to that observed in an OA-resistant guinea pig strain.[193] An inverse relationship between plasma total n-3 fatty acids and DHA and patellofemoral cartilage loss, but not

tibiofemoral cartilage loss or synovitis, has been reported in patients with or at risk of knee OA.[194] Taken together, these studies suggest that n-3 fatty acid supplementation may be beneficial in reducing/preventing structural progression in OA.

To date there are limited human data on the role of n-3 fatty acid supplementation in OA. A 2-year study of high- versus low-dose fish oil used to treat OA revealed clinically significant improvements in pain and disability scores in both groups, with similar improvement at 12 months and greater improvement at 24 months in those receiving low-dose fish oil.[195] This finding suggests that the lower dose of n-3 fatty acids may be appropriate in OA. Further placebo controlled studies of n-3 fatty acid supplementation in OA are warranted.

On the basis of epidemiologic studies, as well as the role of vitamin D in bone health, two clinical trials examining the role of vitamin D supplementation in osteoarthritis have been undertaken. In patients with symptomatic knee OA, no difference was found between oral vitamin D treatment, at doses sufficient to elevate 25-hydroxyvitamin D plasma to higher than 36 ng/mL, and placebo treatment after 2 years with regard to knee pain or MRI-assessed loss of cartilage volume.[196] In a placebo-controlled study of 107 patients with symptomatic knee OA taking 25(OH) vitamin D at greater than or equal to 50 nmol/L, treatment with cholecalciferol 60,000 IU per day for 10 days, followed by 60,000 IU once a month for 12 months resulted in a small but statistically significant reduction in pain and WOMAC scores.[197] Further studies are required to determine the effects of vitamin D supplementation on progression of OA and to better define patients to whom it should be offered.

### Probiotics in the Management of Rheumatic Diseases

**KEY POINT**

**Insufficient data exist to support routine use of probiotics in inflammatory rheumatic diseases.**

Although most interest has focused on the role of probiotics in inflammatory bowel diseases, there are a number of studies in animal models of arthritis, as well as human studies in RA and spondyloarthritis.

Probiotics have been reported to enhance the antiarthritic effects of methotrexate in adjuvant-induced arthritis in rats,[198,199] whereas in collagen-induced arthritis, probiotics downregulated Th1 effector cells, leading to suppression of joint inflammation and reduction in cartilage destruction.[200]

In studies of patients with rheumatic diseases, results have varied depending on the probiotic administered. In a study of 21 patients with RA, 12 months of supplementation with *Lactobacillus rhamnosus* had no effect on disease activity.[201] By contrast, patients with RA who were treated for 8 weeks with *Lactobacillus casei* had a reduction in serum TNF, IL-6, and IL-12, and a reduction in disease activity.[202,203] In a 60-day study of 45 patients with RA, improvement in pain and patient global scores were seen with *Bacillus coagulans* GBI-30 supplements compared with placebo.[204] In 63 patients with active spondyloarthritis, no difference in outcomes was found after 12 weeks of probiotic supplement containing *Streptococcus salivarius*, *Bifidobacterium lactus*, and *Lactobacillus acidophilus* compared with placebo.[205] Alterations in gut microbial flora may influence the absorption and metabolism of drugs. Of particular importance for patients with rheumatic diseases are potential effects on DMARDs, especially sulfasalazine, which is metabolized to the active metabolites sulfapyridine and 5-aminosalicylic acid by intestinal microbes. Probiotics that alter intestinal microflora may potentially alter efficacy and toxicity of sulfasalazine. Although alterations in sulfasalazine metabolism with probiotic supplements have been demonstrated in an animal model, similar effects were not observed in a human study.[206]

In summary, although theoretic considerations and empiric data provide some support for use of probiotics in RA, the evidence is not sufficient to recommend routine use.

## CONCLUSION

Rheumatic diseases are typically chronic, and, as with any chronic disease, nutritional issues are intrinsic to optimization of long-term health. Although patients as individuals can make their own nutritional choices, it is beneficial for rheumatologists to be adequately informed regarding the plausibility and evidence for frequently considered nutritional supplements, toward which this chapter has been directed. In terms of positive advice for patients and referring physicians, the strongest case can be made for dietary supplementation with fish oil in adequate doses for inflammatory arthritis. For long-term analgesia in rheumatic diseases, fish oil can be recommended in favor of NSAIDs. To the extent that fish oil is taken instead of NSAIDs, the risks for serious upper gastrointestinal complications and increased risk for serious thrombotic cardiovascular events associated with NSAIDs can be avoided because fish oil has not been associated with these risks. Furthermore, fish oil has been shown to reduce cardiovascular risks through mechanisms independent of and additional to its NSAID-sparing effects.

CHAPTER 69

# Etiology and Pathogenesis of Rheumatoid Arthritis

Gary S. Firestein

**KEY POINTS**

- Rheumatoid arthritis (RA) is a complex disease involving numerous cell types, including macrophages, T cells, B cells, fibroblasts, chondrocytes, neutrophils, mast cells, and dendritic cells.
- Several genes are implicated in susceptibility to RA and severity of disease, including class II major histocompatibility complex (MHC) genes, *PTPN22,* peptidylarginine deiminases, and many genes that regulate immune responses.
- Evidence of altered immunity, including high serum levels of potentially pathogenic antibodies that bind to modified proteins (e.g., by citrullination), can be present years before the onset of clinical arthritis and result, in part, from environmental stress or the microbiome of mucosal surfaces.
- Adaptive immune responses directed against citrullinated proteins could account for the class II MHC gene associations because the modified peptides bind with high avidity to the RA-associated MHC proteins and can be efficiently presented to T cells.
- Innate immune responses such as complement activation or Toll-like receptor activation can contribute to the initiation and perpetuation of synovial inflammation.
- Stromal elements, especially fibroblast-like synoviocytes, contribute to the pathogenesis of disease by producing cytokines, proteases, and small molecule mediators of inflammation.
- Cytokine networks involving TNF, IL-6, and many other factors participate in disease perpetuation and can be targeted by therapeutic agents.
- Bone and cartilage destruction are primarily mediated by osteoclasts and fibroblast-like synoviocytes, respectively.

Rheumatoid arthritis (RA) is perhaps the most common inflammatory arthritis, affecting from 0.5% to 1% of the general population worldwide. Although the prevalence is surprisingly constant across the globe, regardless of geographic location and race, there are some exceptions. For instance, the occurrence of RA is somewhat lower in China (~0.3%), whereas it is substantially higher in other groups, such as the Pima Indians in North America (~5%). Because of its prevalence and the ready accessibility of joint samples for laboratory investigation, RA has served as a useful model for the study of all inflammatory and immune-mediated diseases. As such, the information gleaned from these studies provides new and unique insights into the mechanisms of normal immunity.

RA is primarily considered a disease of the joints, but abnormal systemic immune responses are evident and can cause a variety of extra-articular manifestations such as vasculitis, nodules, and accelerated atherosclerosis. These manifestations clearly show that RA has features of a systemic disease that can involve many organs. In some cases, autoantibody production with the formation of immune complexes that fix complement contribute to these extra-articular findings. One of the mysteries of RA is why the synovium is the primary target, although the unique structure of its vascular bed could provide an environment that is ideal for innate and adaptive immune responses.

Although the precise causes of RA remain uncertain, environmental and genetic influences clearly are factors. Clues have been provided by detailed immunogenetic studies and the observation that underlying autoimmunity antedates the onset of arthritis by up to a decade. Progress in understanding the pathogenesis has been even more robust: The roles of small-molecule mediators of inflammation (e.g., arachidonic acid metabolites), autoantibodies, cytokines, growth factors, chemokines, adhesion molecules, epigenetics, aberrant signal transduction, and matrix metalloproteinases (MMPs) have been carefully defined. Synovial cells can exhibit aggressive behavior and can invade and destroy articular cartilage, subchondral bone, tendons, and ligaments. Irreversible loss of articular cartilage and bone begins soon after the onset of RA, and early interventions can probably improve long-term outcomes. Increased appreciation of how comorbidities, especially cardiovascular disease and accelerated atherosclerosis, can affect mortality has also led to attempts to suppress synovial and systemic inflammation.

## HOW RHEUMATOID ARTHRITIS BEGINS

The cause and pathogenesis of RA are complex and multifaceted. A variety of predetermined factors (genes) and stochastic factors (random events and environment) contribute to susceptibility and pathogenesis. As an introduction, a summary of how these mechanisms interact to create

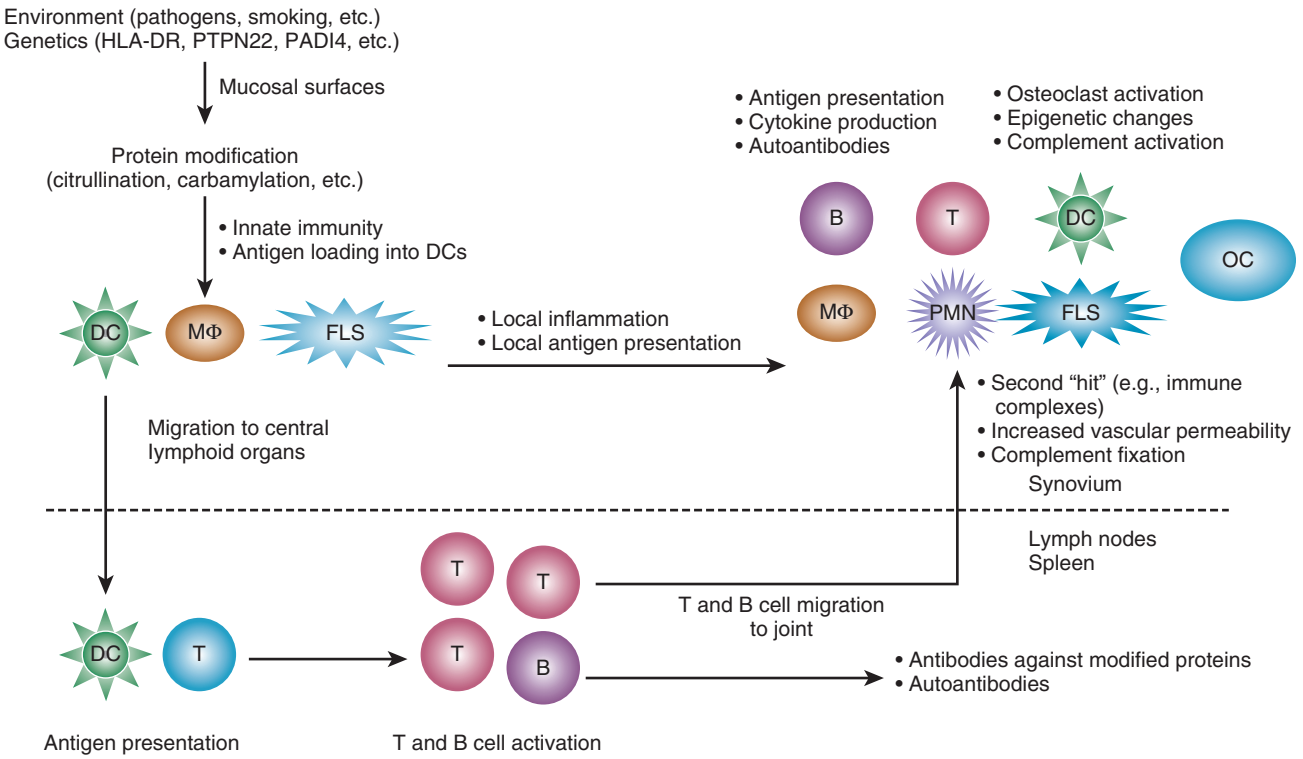

**Figure 69-1** Disease mechanisms that likely occur in rheumatoid arthritis. Innate immunity could activate fibroblast-like synoviocytes (FLS), dendritic cells (DC), and macrophages (MΦ) in the earliest phases in persons with underlying immune hyperreactivity directed toward modified peptides, such as through citrullination with antibody production. The genetic makeup of an individual, including the presence of certain gene polymorphisms in genes that regulate immune responses and environmental exposures, are both required. Chronic inflammation leads to citrullination of proteins in a variety of sites, including mucosal surfaces such as the lungs or the joint. In a genetically susceptible person, these modified peptides are processed by DCs, which can migrate to the central lymphoid organs to present antigen and activate T cells, which can in turn activate B cells. The antibodies can trigger synovial inflammation through a second "hit," perhaps as a result of activation of synovial mast cells by immune complexes. The antibodies can then fix complement in the joint and release chemoattractants that attract lymphocytes to the synovium and enhance adaptive immune responses in the target organ. In addition, repeated activation of innate immunity can directly lead to chronic inflammation and possibly antigen presentation in the synovium. In the latter phases of disease, many cell types activate osteoclasts (OC) through the receptor activator of nuclear factor-κB (NF-κB)/receptor activator of NF-κB ligand (RANK/RANKL) system, although FLS and T cells likely provide the greatest stimulus. Autonomous activation of FLS also might contribute to this process. HLA-DR, Human leukocyte antigen-DR; PADI, peptidyl arginine deiminase; PMN, polymorphonuclear neutrophil.

and perpetuate RA is shown in Figure 69-1. Individual mechanisms are discussed in greater detail throughout the chapter.

The initiation of RA begins years before the onset of clinical symptoms. The onset involves certain specific genes that can lead to the production of pathogenic antibodies that bind to modified proteins, help break tolerance, and lead to autoreactivity. It is likely that the earliest phases are marked by repeated environmental stress, either through toxic exposures or activation of innate immunity (see Figure 69-1).[1] Cigarette smoke, bacterial products, viral components, and other environmental stimuli can contribute to these responses. These stresses induce enzymes that lead to the modification of normal peptides, most commonly through conversion of arginine to citrulline but possibly through other pathways (e.g., the conversion of lysine to homocitrulline).

This circumstance occurs often in healthy persons, although some populations, most notably Asians, have genetic associations that can favor increased citrullination through increased expression of peptidyl arginine deiminase (PADI) 4. In most people the process is self-limited and has no untoward effects. However, in people with class II major histocompatibility complex (MHC) genes implicated in RA, these altered peptides bind very tightly into the antigen-binding groove and are presented to T cells far more efficiently than the native unmodified protein. Because T cells are not exposed to the altered peptide during development, they are not deleted in the thymus and can respond with a normal adaptive immune response directed against these new epitopes.

These exposures most likely occur at mucosal surfaces, such as the lung, gut, and oral cavity, although modification of peptides also can occur in the synovium itself. Altered peptides are loaded into dendritic cells (DCs), and antigen presentation has the potential to occur in the synovial germinal centers or, more commonly, in central lymphoid organs after the loaded DCs migrate via the lymphatics. T cells are activated and can produce pathogenic cytokines such as IL-17 at these sites and help B cells produce antibodies. These antibodies are most commonly directed against citrullinated peptides but could also recognize other altered peptides, such as through carbamylation. The anti-citrullinated protein antibodies (ACPAs) are produced

against a variety of proteins, including fibronectin, vimentin, α-enolase, histones, and many others.

Over a period of years, the titers of ACPAs with broad specificity increase many fold.[2] There is not an individual "RA-associated" ACPA but instead a general rise of the many different antibodies. Findings of synovial biopsies during the pre-RA time, even if individuals have arthralgias, are essentially normal.

The ACPAs themselves are not sufficient to initiate synovitis, and a "second hit" is clearly necessary. The nature of the second signal is not well defined, but in animal models it can occur with the formation of immune complexes. These complexes do not have to be specific for altered peptides but can actually be totally irrelevant, such as to viruses or other xenoantigens. They can engage Fc receptors in the synovium, especially on mast cells, which lead to local release of vasoactive mediators and increase access of ACPAs to the joint. Once in the joint, if they encounter their antigen, they can fix complement and initiate a cascade of events leading to recruitment of innate and adaptive immune cells, production of additional cytokines and chemokines, and activation of local fibroblast-like synoviocytes (FLS) and macrophages. As the cells are recruited and activated, ultimately a tipping point is reached and clinical synovitis ensues.

Additional genetic associations amplify the normal adaptive response to modified proteins, true autoreactivity against the native proteins through epitope spread, or local synovial inflammatory responses. T cell signaling polymorphisms can favor these events (e.g., protein tyrosine phosphatase-22 [PTPN22]). Cytokine promoter polymorphisms, signal transduction gene polymorphisms, and other genetic markers also could provide positive feedback to enhance the response. Epigenetic changes that imprint synovial cells through DNA methylation, microRNA (miRNA) production, or histone modification can enhance local immune dysregulation.

Ultimately, a destructive phase proceeds, which can have antigen-dependent and antigen-independent mechanisms and is mediated by mesenchymal elements such as fibroblasts and synoviocytes. Bone erosions are subsequently caused by activated osteoclasts, whereas cartilage dissolution results from proteolytic enzymes produced by synoviocytes in the pannus or synovial fluid neutrophils. Anti-inflammatory mechanisms such as soluble TNF receptors, suppressive cytokines, cytokine-binding proteins, protease inhibitors, lipoxins, antioxidants, anti-angiogenic factors, and natural cytokine antagonists are not present in sufficient concentrations to truncate the inflammatory and destructive process. Suppressing this response requires therapeutic interventions that either modulate pathogenic cells or neutralize the effector molecules produced by the rheumatoid process, or restore tolerance.

Highly targeted therapeutics to individual cytokines, mediators, or cell lineages demonstrate remarkably diverse clinical responses. Although overlap exists, some patients have cytokine-dependent disease (e.g., TNF or IL-6), some have B cell–dependent disease, and others have T cell–dependent disease. These clinical observations suggest that RA is not a single pathogenic entity but is instead a collection of disorders that varies depending on the genetic makeup and environmental triggers for an individual patient. By understanding the basic mechanisms of disease, we can begin to untangle which RA a particular person might have and how to personalize therapy.

## ETIOLOGY

**KEY POINTS**

- **Genes play a key role in RA susceptibility and severity.**
- **Class II MHC genes, especially those with certain sequences in the antigen-binding groove, are the most prominent genetic associations.**
- **The human leukocyte antigen (HLA)-DR associations could be related to efficient binding and presentation of modified peptides.**
- **Newly defined genetic associations in more than 100 genes including polymorphisms in *PTPN22*, *PADI4*, and genes involved in immune function suggest that the associations in RA are complex and involve many pathways.**
- **The microbiome and environmental stress at mucosal surfaces contribute to the etiology of RA.**

Although the cause of RA remains unknown, the interaction of environmental and genetic factors is almost certainly responsible; either one is necessary but not sufficient for full expression of the disease. The most compelling evidence for a genetic component is in monozygotic twins, in whom the concordance rate is perhaps 12% to 15% when one twin is affected, compared with 1% for the general population. The fact that concordance is not higher provides key evidence that other influences such as the environment, epigenetics, or microchimerism from maternal-fetal transfer might be as important as or even more important than the genetic component. The risk for a fraternal twin of a patient with RA is also high (~2% to 5%) but similar to the rate for other first-degree relatives.

Although the immunogenetics is not fully understood, one of the best-studied and perhaps most influential genetic risk factors is the class II MHC haplotype of an individual. Single nucleotide polymorphisms (SNPs) in *PTPN22* and *PADI4* increase risk in some (but not all) racial and ethnic groups. Genome-wide screens have implicated more than 100 genes, many of which are involved with immune function.[3] However, most genes have a relatively modest contribution, and the susceptibility polymorphism confers only a 1.05- to 1.2-fold increase. Combinations of genes can clearly interact with one another, and a 45-fold increase in risk is conferred by a combination of *HLA-DR*, *PTPN22*, and the *TRAF1-C5*.[4] However, this combination is found in less than 1% of persons with RA, and algorithms of RA other SNPs have not yet identified a critical combination that can account for the disease. Additional progress in understanding the role of genes in RA, including rare variants that might be more important than some common polymorphisms, will require sophisticated bioinformatics to clarify how individual alleles contribute to susceptibility, severity, and response to targeted therapies.

## Role of Human Leukocyte Antigen-DR in the Disease Susceptibility and Severity

The structure of class II MHC molecules on antigen-presenting cells is associated with increased susceptibility and severity of RA and accounts for about 40% of the genetic influence. A genetic link between HLA-DR and RA was initially described in the 1970s with the observation that HLA-DR4 occurred in 70% of patients with RA, compared with about 30% of control subjects, giving a relative risk of having RA to those with HLA-DR4 of approximately 4-fold to 5-fold.

The susceptibility to RA was originally ascribed to an association with the third hypervariable region of DRβ chains, from amino acids 70 through 74. The epitope is glutamine-leucine-arginine-alanine-alanine (QKRAA), a sequence found in DR4 and DR14, in addition to some DR1β chains. The "susceptibility epitope" (SE) on DR4β chains with the greatest association with RA are DRB*0401, DRB*0404, DRB*0101, and DRB*1402 (Table 69-1). Up to 96% of patients with RA exhibit the appropriate HLA-DR locus in some populations.[5] In certain ethnic and racial groups, the association with QKRAA is not as prominent. The QKRAA epitope also predicts increased severity of established RA, with a greater prevalence of extraarticular disease and erosions in patients with two copies. Other HLA genes such as DRB*1301 contain the DERAA sequence and are associated with decreased susceptibility to RA.[6]

One intriguing possibility that could account for some patients who do not fit within this paradigm is microchimerism.[7] Maternal cells expressing the SE have the potential to survive and persist in the circulation throughout adulthood. These noninherited maternal antigens could then confer increased risk of disease in the children of women who express SE.

The region associated with RA (QKRAA) primarily faces away from the antigen-binding cleft of the DR molecule that determines the specificity of peptides presented to $CD4^+$ T helper (Th) cells. Attempts to elute peptides from the binding pocket of RA-associated alleles have not revealed a single antigen that is either unique to or associated with RA. The SE also plays a role in shaping the T cell repertoire in the thymus or altering intra-cellular HLA-DR trafficking and antigen loading, which could contribute to the association. Alternatively, QKRAA could serve as an autoantigen as a result of molecular mimicry in some situations because some xenoproteins such as gp110 from the Epstein-Barr virus (EBV) also include this sequence.

More recent informatics approaches to the role of the SE suggest that the most prominent association is actually with amino acids 11 and 13.[8] These residues lie in the bottom of the antigen-binding groove of HLA-DR. A leucine or valine at amino acid 11 is associated with increased risk of developing disease, whereas serine at amino acid 13 confers decreased risk. These key residues could play a major role selecting "arthritogenic" peptides. In fact, careful studies of antigen-binding affinities show that citrullinated vimentin peptides bind much more avidly to the RA-associated alleles than the unmodified protein. HLA-DR genes that are not associated with RA do not display this disparity. Functional studies show that these same RA-associated alleles present antigen more efficiently to T cells with higher amounts of cytokines such as IL-17 and interferon (IFN)-γ.[9,10]

Based on these observations, the shared epitope might not be considered an independent risk factor for RA but instead a marker for immunoreactivity to altered peptides that lead to ACPAs.[11] In a large series of patients with early undifferentiated inflammatory arthritis, one-third of patients met criteria for RA within 1 year. Progress to RA occurred regardless of HLA-DR genotype if patients were $ACPA^+$. When patients were stratified according to ACPA, the shared epitope did not make an additional contribution to progression from undifferentiated arthritis to RA. In other studies, however, the presence of the shared epitope and ACPAs together is associated with even greater disease severity, indicating that the role of MHC might be more complex.

**TABLE 69-1** Nomenclature for Human Leukocyte Antigen-DR Alleles and Associations with Rheumatoid Arthritis

| Old Nomenclature (HLA-DRB1 Alleles) | Current Nomenclature | Association with RA |
|---|---|---|
| HLA-DR1 | 0101 | + |
| HLA-DR4 Dw4 | 0401 | + |
| HLA-DR4 Dw14 | 0404/0408 | + |
| HLA-DRw14 Dw16 | 1402 | + |
| HLA-DR4 Dw10 | 0402 | – |
| HLA-DR2 | 1501, 1502, 1601, 1602 | – |
| HLA-DR3 | 0301, 0302 | – |
| HLA-DR5 | 1101-1104, 1201, 1202 | – |
| HLA-DR7 | 0701, 0702 | – |
| HLA-DRw8 | 0801, 0803 | – |
| HLA-DR9 | 0901 | – |
| HLA-DRw10 | 1001 | – |
| HLA-DRw13 | 1301-1304 | 1301 associated with protection |
| HLA-DRw14 Dw9 | 1401 | – |

HLA, Human leukocyte antigen; RA, rheumatoid arthritis.

## Additional Polymorphisms: Cytokines, Citrullinating Enzymes, *PTPN22*, and Others

The genetic influence on RA has also led to studies evaluating non-MHC genes. SNPs in promoter regions, coding regions, or areas with no known function have been extensively investigated in RA with a variety of methods, including genome-wide association studies. Table 69-2 shows some of the SNPs and microsatellites that have been associated with RA. The relative contribution for most is modest, and variations in technique, stage of disease, and patient populations result in some disagreement among various reports.

Given the importance of cytokines in RA, it is not surprising that many studies have focused on these genes.

**TABLE 69-2** Key Genetic Associations in Rheumatoid Arthritis

| Gene | Odds Ratio for Risk Alleles | Comment |
|---|---|---|
| *HLA-DR* | 4- to 5-fold | |
| *PTPN22* | ~2-fold | Not in Asian populations |
| *PADI4* | ~2-fold | Primarily in Asian populations |
| *TRAF1-C5* | From 1.2-fold to 2-fold | |
| *STAT4* | From 1.2-fold to 2-fold | |
| *TNFAIP3* | From 1.2-fold to 2-fold | |
| *IL2/21* | From 1.2-fold to 2-fold | |

Examples of genes with an odds ratio >1.0 and <1.2: *CTLA4, CD40, CCL21, CD244, IL2Rb, TNFRSF14, PRKCQ, PIP4K2C, IL2RA, AFF3, REL, BLK, TAGAP, CD28, TRAF6, PTPRC, FCGR2A, PRDM1, CD2-CD58, IRF5, CCR6, CCL21, IL6ST,* and *RBPJ.*

The most intriguing evidence relates to TNF. This proinflammatory factor is a major cytokine in the pathogenesis of RA, and the TNF genes are located in the MHC locus on chromosome 6 in humans. Several polymorphisms of the TNF promoter, including positions −238 and −308, can alter gene transcription. Associations among the TNF polymorphisms and RA susceptibility and radiographic progression have been reported, although agreement is not uniform. In addition, certain polymorphisms in cytokines, especially TNF or Fc receptors, have been associated with a differential response to therapy. For instance, substitution of a T for a C at position −857 in the TNF promoter might confer greater responsiveness to TNF inhibitors.[12] IL-6 receptor polymorphisms that affect IL-6 function have also been associated with RA.[13]

Among the many noncytokine and non-MHC genetic linkages described for RA, the ones associated with *PADI* and *PTPN22* have the strongest effect on susceptibility. The *PADI* genes are responsible for the post-translational modification of arginine to citrulline and creating the neoantigens that bind so efficiently to RA-associated MHC proteins. PADIs also have other less well-characterized functions, such as citrullination of histones that can then remodel chromatin. Four isoforms known as *PADI1* through *PADI4* have been identified. An extended *PADI4* haplotype that can lead to increased levels of PADI4 protein as a result of enhanced messenger RNA (mRNA) stability is associated with RA.[14] In a Japanese cohort, a twofold increase in risk of RA was observed with *PADI4* SNPs. Similar studies confirm the association in Asian populations, and more recent data suggest that it is also a risk gene in North America.

PTPN22 associations have been discovered in large-scale screening efforts to identify SNP associations in RA.[15] An association at position 1858 in the *PTPN22* gene confers a twofold increase in risk. The allele containing thymidine leading to an amino acid substitution (R620W) was present in 8.5% of control subjects but was found in nearly 15% of patients with seropositive RA. Other studies have demonstrated a similar association with systemic lupus erythematosus (SLE), type 1 diabetes, and several other autoimmune diseases. *PTPN22* encodes a phosphatase that regulates the phosphorylation status of several kinases important to T cell activation, including Lck and ZAP70. The R620W allele surprisingly results in a gain of function that alters the threshold for T cell receptor (TCR) signaling. Because the *PTPN22* allele is rare in Japan, other genes (e.g., *PADI4*) influence susceptibility in this and other particular ethnic or racial populations.

The genes associated with RA consistently involve immune regulation, and many are commonly shared with other immune-mediated diseases such as SLE, type 1 diabetes, and celiac disease.[16] Cytokine polymorphisms such as for TNF and the IL-1 inhibitor, IL-1Ra, are not surprising. Genes that regulate adaptive immune responses in T cells such as *PTPN22* and the co-stimulation receptor CTLA have also been associated with RA. Other genes associated with B cell function and/or antigen presentation such as *BTLA* (B- and T-lymphocyte attenuator), Fc receptors, and *CD40* are also implicated. Polymorphisms have also been identified in signal transduction pathways that regulate immune function such as TRAF1-C5 and signal transducer and activator of transcription (STAT) 4, cell migration *(ELMO1)*, and fetal development *(LBH)*. The consistent thread in this analysis is that most gene associations for RA cluster to innate immunity, adaptive immunity, matrix regulation, and inflammation. Aside from providing insight into the mechanisms of disease, they could also contribute to responses to targeted therapies.

## Interactions between Genes and Environment

A number of environmental factors clearly contribute to RA susceptibility, and a low level of vitamin D recently has been associated with increased risk.[17] Microchimerism, including male microchimerism in women, also has been associated with increased risk.[18] However, smoking is the best defined environmental risk factor. The reason for its influence on the development of synovitis is not fully defined but could involve the activation of innate immunity and *PADI* in the airway. Smoking induces PADI expression in the airway and increases protein citrullination, which could provide a stimulus for generation of ACPAs in susceptible persons[19] (Figure 69-2). High-resolution computed tomography studies demonstrate associations between ACPA formation and bronchial thickening in the pre-RA stages, suggesting that the local inflammatory response could begin at this mucosal site.[20] Other environmental factors such as oral contraceptives appear to provide modest protection from RA, perhaps as a result of changes in the hormone milieu.[21]

The interaction between HLA-DR and tobacco exposure is perhaps the best example of how genes and the environment conspire to enhance risk. Although smoking and the SE alone modestly increase the likelihood of developing RA, the combination is synergistic.[22] A person with a history of cigarette smoking and two copies of the SE increases the odds of developing RA by up to 40-fold. The mechanism of the interaction probably relates to increased protein citrullination in smokers and the ability of SE-containing HLA-DR molecules to present citrullinated proteins. The extent of smoking is also predictive, with the greatest risk seen with at least 20 pack-years. The risk declines slowly with cessation of smoking, taking more than a decade to begin approaching the risk in nonsmokers.[23] Alcohol consumption can decrease this risk, and exposure

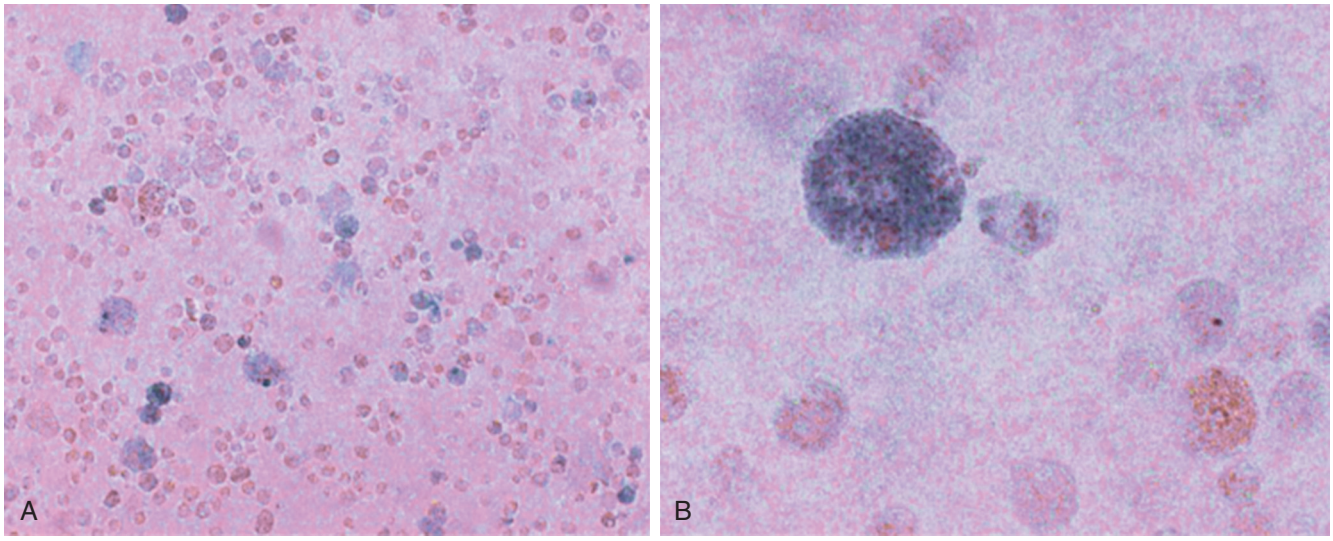

**Figure 69-2** Citrullinated proteins in alveolar macrophages in smokers. Immunostaining of alveolar macrophages from the bronchoalveolar lavage in smokers shows citrullinated proteins *(blue-brown color)*. Nonsmokers do not have significant staining. *(From Klareskog L, Stolt P, Lundberg K, et al: A new model for an etiology of rheumatoid arthritis: smoking may trigger HLA-DR [shared epitope]-restricted immune reactions to autoantigens modified by citrullination.* Arthritis Rheum *54:38–46, 2006.)*

to other inhaled irritants such as silica dust increases risk, demonstrating the complexity of the environment and human behavior on understanding disease susceptibility. Diet is also a potential risk, and obesity could contribute to disease susceptibility through the production of adipokines (for a detailed discussion of nutrition and RA risk see Chapter 68).[24]

## Microbiome

The observation that airway inflammation might contribute to disease risk has led to various studies to evaluate contributions at other mucosal sites. Similar associations are observed in animal models of arthritis, where arthritis susceptibility and severity can be lower in rodents raised in a germ-free or defined bacteria environment. The most prominent association is with periodontitis, commonly caused by *Porphyromonas gingivalis*. This bacterium is one of the few that produces its own PADI, which could lead to local citrullination of proteins such as fibronectin. More recent data suggest that *P. gingivalis* can also act by stimulating Toll-like receptor (TLR)2, which increases IL-1 production and leads to production of pathogenic Th17 cells.[25] In the gut, expansion of *Prevotella copri* species occurs in patients with early-stage RA, with a concomitant decrease in *Bacteroides*.[26] These differences are not seen in long-standing RA, although it is not clear whether that is a result of treatment or other factors that might alter the gut microbiome. Regardless, the interactions between host and bacteria, even nonpathogenic commensals, could play a major role in immune-mediated diseases like RA.

## Sex

RA is one of many chronic autoimmune diseases that predominates in women. The ratio of female-to-male patients is 2 : 1 to 3 : 1, which is not as high as Hashimoto's thyroiditis (25 : 1 to 50 : 1) or SLE (9 : 1). The sex effect is often observed in some animal models of autoimmunity such as the NZB/NZW model of SLE, in which female mice have more severe disease. Estrogens are one obvious explanation, and some data support the concept that these hormones modulate immune function.[27] For example, autoantibody-producing B cells exposed to estradiol are more resistant to apoptosis, suggesting that autoreactive B cell clones might escape tolerance. Estrogen receptors are expressed on FLS and increase production of metalloproteinases. In macrophage cell lines, estrogen can enhance production of TNF. Spontaneous arthritis occurs in mice with a specific mutation in the *ZAP70* gene, which regulates T cell responses. Exogenous administration of estrogen actually ameliorates disease, suggesting that the interactions between sex hormones and disease are complex.[28] Nulliparity has also been suggested as a risk factor in early studies, but more recent reports do not support this notion. Thus the specific mechanisms responsible for the female preponderance of RA are not fully understood.

Pregnancy is often associated with remission of the disease in the last trimester. More than three quarters of pregnant patients with RA improve in the first or second trimester, but 90% of these women experience a flare of disease associated with a rise in rheumatoid factor (RF) titers in the weeks or months after delivery. The mechanism of protection is not defined but might be due to the expression of suppressive cytokines such as IL-10 during pregnancy, production of α-fetoprotein, or alterations in cell-mediated immunity. One intriguing finding is that fetal DNA levels in the maternal peripheral blood correlate with the propensity for improved symptoms in pregnant women with RA. It is not certain whether the DNA itself contributes or whether it is a marker for increased leakage of fetal cells into the maternal circulation.[29] Immune responses directed against paternal HLA antigens can occur and lead to the production of alloantibodies in the maternal circulation. Maternal-fetal disparity in class II HLA phenotypes can correlate with pregnancy-induced remission. More than

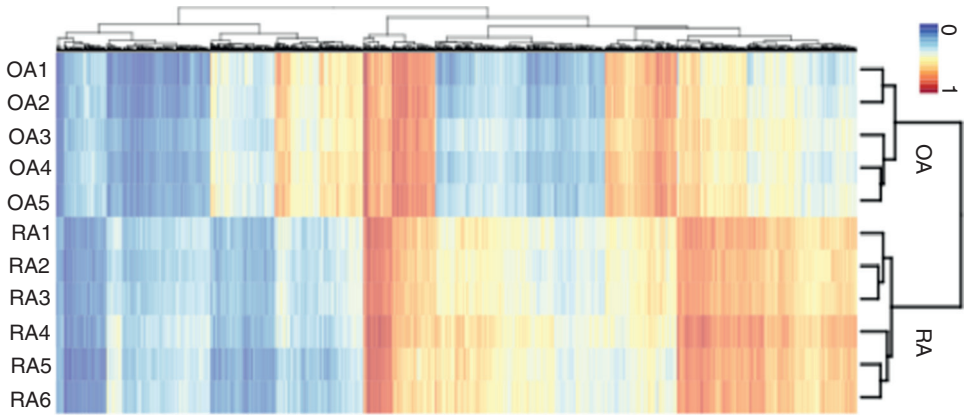

**Figure 69-3** Abnormal DNA methylation in fibroblast-like synoviocytes (FLS). Using chip technology, the methylation pattern of DNA from osteoarthritis (OA) and rheumatoid arthritis (RA) FLS was determined. Note that the cells from the two diseases segregate based solely on the methylation pattern. The methylation signature is stable and involves many genes involved in immune responses. *(From Nakano K, Whitaker JW, Boyle DL, et al: DNA methylome signature in rheumatoid arthritis.* Ann Rheum Dis *72:110–117, 2013.)*

three-fourths of pregnant women with maternal-fetal disparity of HLA-DRB1, DQA, and DQB haplotypes have significant improvement, whereas disparity is only observed in one-fourth of women whose pregnancy is characterized by continuous active arthritis.[30] Therefore, suppression of maternal immune responses to paternal HLA haplotypes might be protective. This question remains unsettled because another study failed to find a correlation between the HLA disparity and clinical improvement during pregnancy.[31]

## Epigenetics

Epigenetics describes phenotypic or gene expression properties caused by mechanisms other than changes in the underlying DNA sequence. Modification of cytosine-phosphatidyl-guanine (CpG) DNA sequences by methylation, for example, can suppress gene expression and plays a role in cell differentiation. Histone acetylation also alters accessibility of DNA for transcription factors and RNA polymerases. miRNAs can bind to DNA and suppress expression of key genes involved with the inflammatory process. Epigenetic information such as DNA methylation can be transferred from one generation to the next, thereby providing an alternative mechanism for rapidly altering disease susceptibility in a population as a result of the environment.

Some data from peripheral blood studies suggest that a modest overall decrease in methylation occurs in RA mononuclear cells. However, the data are difficult to interpret because blood mononuclear cells are a mixture of different cell types, and epigenetic signatures in one lineage could be diluted out by other cells. Most information on epigenetics in RA comes from studies of RA synovium or cultured synoviocytes. Individual candidate genes, such as *IL6*, *CXCL12*, and ephrin-B1 *(EFNB1)* are hypomethylated, whereas others, like *HLA-DRB3*, *EBF2*, and *IRX1*, have an increased number of methylated loci.[32] Unbiased approaches using chip technology suggest that the overall level of methylation in RA FLS is not different from osteoarthritis (OA) or normal cells. However, there are clear patterns of differential methylation in RA, with some loci being hypermethylated, whereas others are hypomethylated (Figure 69-3).[33]

Differential methylation in FLS is stable over many cell passages, and detailed analysis indicates that the differentially methylated genes are enriched in pathways such as cell adhesion, focal adhesion, matrix regulation, cytokine-cytokine receptor interactions, and other functions important to immune function. A portion of this signature could be due to the local cytokine milieu, because IL-1 can suppress expression of DNA methyl transferases. The effect of cytokines is transient in culture, and the cells return to baseline after the cytokine is removed. These data suggest that permanent imprinting of FLS in RA could be due to other factors and could even be inherited.[34] Dietary influences—for example, ingestion of methyl donors such as folate—or even exposure to methyl donors in utero can also profoundly alter DNA methylation and adaptive immune functions.

Few data are available on histone marks in RA. However, histone deacetylases are expressed in RA FLS, and histone deacetylase HDAC1 is overexpressed.[35] The use of small interfering RNA to knock down HDAC1 or HDAC2 increases expression of the p53 tumor suppressor gene and TNF-induced expression of MMP-1.[36] Cytokines such as TNF can increase HDAC1 expression in cultured FLS. SIRT1 also exhibits HDAC activity and is overexpressed in RA FLS and synovium. Blocking SIRT1 in FLS reduces IL-6 and IL-8 production. HDAC inhibitors are also effective in several animal models of arthritis, including adjuvant arthritis in rats and collagen-induced arthritis in mice.[37] These data indicate that histone marks can play a key role in remodeling the chromatin to increase production of inflammatory mediators in RA.

Analysis of synoviocytes shows that several miRNAs such as miRNA-124a are decreased in RA compared with OA cells. This particular miRNA can suppress cell cycling and chemokine genes. Increasing miRNA-124a levels in RA synoviocytes decreased the production of the chemokine macrophage chemoattractant (MCP)-1.[38] Forced expression of miRNA-203 increases metalloproteinase and

IL-6 expression by synoviocytes as well.[39] miRNA-155 is especially interesting because it is overexpressed in RA synovial cells and peripheral blood cells. Knocking down this miRNA reduces MMP and cytokine expression in these cells. In vivo miRNA-155 deficiency has mixed effects in animal models, with decreased severity in collagen-induced arthritis and no effect in the passive K/BxN serum transfer model.[40] The differences in the two models might result from distinct mechanism of disease; the latter is purely a model of innate immunity, whereas adaptive immunity plays a prominent role in the former. Several other miRNAs are differentially expressed in RA, including miRNA 16, 124a, 202, 134a, 23, 346, and 15a.[41] Ultimately, unbiased profiling using technologies will be needed to fully assess how miRNA patterns influence disease pathogenesis in RA.

The role of epigenetics in RA is not completely understood. It is not clear whether these observations occur before the onset of disease, are involved with the transition from asymptomatic autoimmunity to clinical disease, or participate in the destructive phase in established RA. Environmental stress plays a major role in disease susceptibility—perhaps a greater role than DNA polymorphisms. The mechanisms probably involve epigenetic dysregulation of gene expression, leading to decreased thresholds for autoreactivity in the adaptive immune system.

## Changing Epidemiology

The history of RA reveals the surprising observation that it is a relatively new disease in Europe and Northern Africa. Examination of ancient skeletal remains in Europe and Northern Africa fails to reveal convincing evidence of RA, even though other rheumatic diseases such as OA, ankylosing spondylitis, and gout are readily discernable. In contrast, typical marginal erosions and rheumatoid lesions are present in the skeletons of Native Americans found in Tennessee, Alabama, and Central America from thousands of years ago. The first clear descriptions of RA in Europe appeared in the seventeenth century, and the disease was distinguished from gout and rheumatic fever by Garrod in the mid nineteenth century. Although the theory is still controversial, the disease might have migrated from the New World to the Old World coincident with opening of trade and exploration routes. Because genetic admixture was relatively limited, an undefined environmental exposure, in collaboration with risk-associated MHC genes, potentially caused RA in susceptible Europeans. The most obvious explanation, of course, would be that an infectious agent is responsible. However, other environmental influences such as tobacco smoking were also introduced to the Old World at the same time and could play a role. Recent data implicating smoking-induced citrullination of proteins in the airway are especially intriguing clues to the introduction of RA in Europe.

The severity and incidence of RA appeared to decrease in the late twentieth century (Figure 69-4).[42] In certain well-defined populations, including Native Americans, the incidence of RA has gradually declined by as much as 50% during the past half of the twentieth century. However, when this Olmsted County cohort was extended into the early twenty-first century, the trend reversed.[43] The age-adjusted increase occurred in all age groups but mainly occurred in women.[43] Because smoking has decreased in the United States, a change in tobacco use is probably not the explanation. Other influences such as hygiene and other lifestyle modifications related to industrialization might contribute, and an infectious agent might have variable prevalence as a result of these societal changes, as with many other infectious diseases. Currently the lifetime risk of developing RA is remarkably high—namely, 3.6% in women and 1.7% in men.[44] The second most common autoimmune rheumatic disease is polymyalgia rheumatica, with a lifetime risk of 2.4% in women and 1.4% in men.

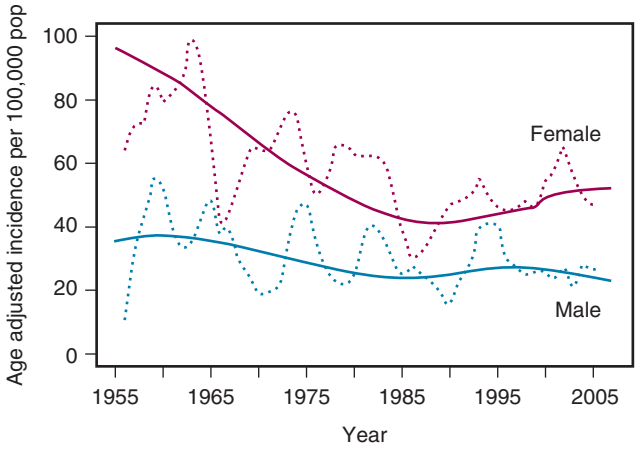

**Figure 69-4** Population studies in Minnesota demonstrated a gradually decreasing incidence of rheumatoid arthritis from 1960 to 1995. However, the trend appears to have reversed from 1996 to 2007 in women. *(From Myasoedova E, Crowson CS, Kremers HM, et al: Is the incidence of rheumatoid arthritis rising? Results from Olmsted County, Minnesota, 1955-2007.* Arthritis Rheum *62:1576–1582, 2010.)*

# PATHOGENIC MECHANISMS

**KEY POINTS**

- **Although an etiologic link has not been established, pathogens such as viruses, retroviruses, bacteria, and mycoplasma have been associated with RA.**
- **A single specific "RA pathogen" is unlikely, although the microbiome at mucosal surfaces plays a key role.**
- **Repeated inflammatory stress, especially through specialized receptors that recognize common molecules produced by pathogens in a genetically susceptible individual, might contribute to altered peptides through citrullination, breakdown of tolerance, and subsequent autoimmunity.**

Considerable effort has been expended to assess the role of infectious agents in RA (Table 69-3). A potential pathogen could initiate disease through a variety of mechanisms, including direct infection of the synovium, activation of innate immunity by pattern-recognition receptors that bind to components of the agent, or through molecular mimicry that induces an autoreactive adaptive immune response.

**TABLE 69-3** Etiology of Rheumatoid Arthritis: Role of Infection

| Infectious Agent | Potential Pathogenic Mechanisms |
|---|---|
| *Mycoplasma* | Direct synovial infection; superantigens |
| Parvovirus B19 | Direct synovial infection |
| Retroviruses | Direct synovial infection |
| Enteric bacteria | Molecular mimicry (QKRAA, e.g., in bacterial heat shock proteins) |
| *Mycobacteria* | Molecular mimicry (proteoglycans, QKRAA), immunostimulatory DNA (Toll-like receptor 9 activation) |
| Epstein-Barr virus | Molecular mimicry (QKRAA in gp110) |
| Bacterial cell walls | Toll-like receptor 2 activation |
| *Porphyromonas gingivalis* | Toll-like receptor 2 activation and protein citrullination |
| *Prevotella* sp. | Altered gut microbiome |

## Infectious Agents: Direct Infection and Innate Immune Responses

As previously noted, bacteria and other pathogens have been indirectly implicated in RA. The interactions between the microbiome and mucosal surfaces in RA indirectly contribute, possibly by modifying proteins or shaping the T cell repertoire. In this section, a more direct role of pathogens in the initiation and propagation of RA is discussed.

### Toll-like Receptors and the Inflammasome in the Joint

Infectious agents could contribute to the initiation or perpetuation of RA through a variety of mechanisms. Some arthrotropic microorganisms could infect the synovium and cause a local inflammatory response. There is increasing awareness that the innate immune system could also directly affect the onset and course of synovitis. Pathogen-associated molecular pattern receptors, especially the TLRs, are expressed by sentinel cells in the host that provide a first line of defense (see Chapter 17). These receptors recognize preserved structures in bacteria and other infectious agents and permit rapid release of inflammatory mediators, activation of antigen-presenting cells, and enhancement of adaptive immune responses.

At least 11 TLRs exist in humans, such as TLR2 (which binds peptidoglycans), TLR3 (which binds double-stranded RNA [dsRNA]), TLR4 (which binds lipopolysaccharide [LPS]), and TLR9 (which binds bacterial DNA containing CpG motifs). Many of these pattern recognition receptors are expressed by rheumatoid synovial tissue and cultured FLS including TLR2, TLR3, TLR4, and TLR9. Exogenous TLR ligands such as bacterial peptidoglycan and DNA, as well as endogenous ligands (e.g., heat shock proteins [HSPs], fibrinogen, and hyaluronan), are present in arthritic joints (see the subsequent discussion). Engagement of these receptors participates in certain animal models of arthritis and can exacerbate synovial inflammation, and their absence can limit or prevent arthritis. TLR3, which recognizes viral dsRNA and activates the anti-viral response, is also expressed by synovial cells in the intimal lining. Necrotic debris containing mRNA from RA synovial fluid cells activates TLR3 signaling and pro-inflammatory gene expression in synovitis.

The role of innate immunity in RA led to the notion that repeated engagement of TLRs in the synovium could help initiate or exacerbate disease. This hypothesis could explain why specific pathogens have been difficult to identify in the joint, and could mainly participate by increasing vascular permeability and ingress of pathogenic antibodies (e.g., ACPAs). In contrast, a genetically susceptible person could potentially break tolerance if the TLRs are repeatedly engaged and permit autoimmune responses against articular antigens. Several animal models of disease require TLR ligands for initiations, such as TLR9 in adjuvant arthritis. TLR2 is required for streptococcal cell wall arthritis, and the chronic T cell–dependent phase of that model requires TLR4. Mice lacking TLR4 have significantly less joint damage induced by IL-1 overexpression, even though synovial inflammation is still robust.[45] These data suggest that endogenous TLR ligands play a key role in matrix regulation independent of inflammatory responses.

A second mechanism that regulates innate immunity involves the inflammasome. This complex includes several proteins involved in recognition of "danger signals" and products of pathogens such as muramyl dipeptides and uric acid. One central component is cryopyrin, also called NALP3, which is linked to caspase 1 (IL-1 convertase) by adapter proteins. When the inflammasome is engaged, caspase 1 is activated and IL-1 is processed and released. Mutations in this pathway, especially in cryopyrin, have been associated with autoinflammatory disorders such as Muckle–Wells syndrome and familial cold autoinflammatory disease. Inflammation induced by uric acid crystals or adenosine triphosphate uses this pathway and can be abrogated by IL-1 inhibitors. Cryopyrin is abundant in RA synovium and is constitutively expressed by FLS and macrophages. Other inflammasome components and related genes are highly expressed in RA peripheral blood cells, including ASC, MEFV, and cryopyrin-NALP3.[46] Expression in cultured FLS is markedly increased by TNF. In addition, a cryopyrin/NALP3 SNP might be associated with increased risk of RA. Because the TNF-induced inflammasome activation can induce cytokine production after exposure to bacterial products and other danger signals, it could participate in synovial IL-1 and IL-18 regulation.

### Bacteria, Mycobacteria, Mycoplasma, and Their Components

Active infection of synovial tissue by pyogenic bacteria is an unlikely cause of RA, and extensive searches for a unique or specific organism in synovial tissue or joint effusions have been negative. Antibodies to certain organisms such as *Proteus* are reportedly elevated in the blood of patients with RA, but this finding could represent nonspecific B cell activation. Most patients with RA and reactive arthritis contain bacterial DNA sequences in their synovium. The bacteria identified are not unique and generally represent a cross-section of skin and mucosal bacteria, including *Acinetobacter* and *Bacillus* spp. The accumulation of bacterial products is probably due to phagocytosis by local macrophages.

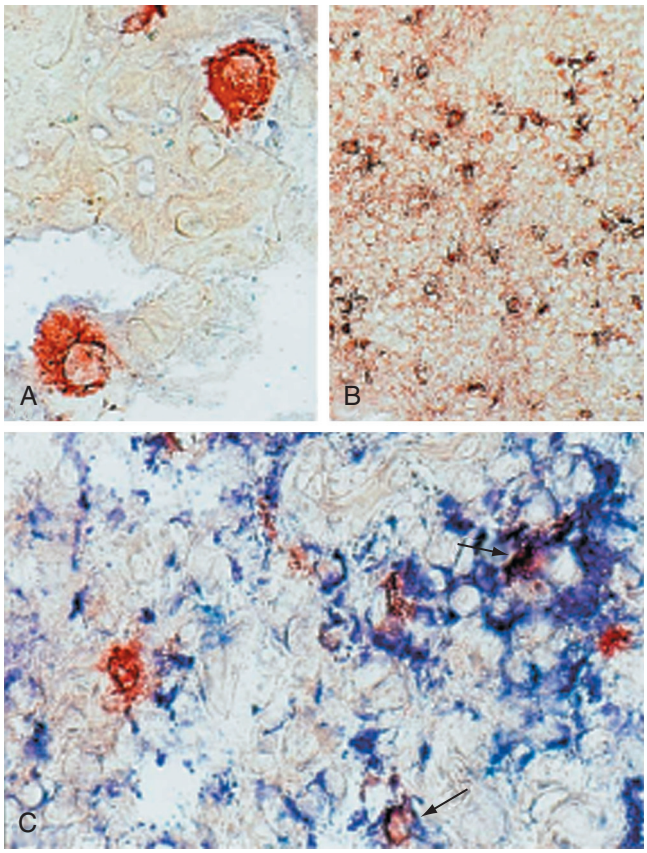

**Figure 69-5** Accumulation of bacterial peptidoglycan in rheumatoid synovium. **A** and **B,** Immunohistochemistry shows synovial cells containing peptidoglycan *(red)*. **C,** Double staining studies show that bacterial peptidoglycan accumulates in synovial macrophages *(arrows)*. These bacterial products can activate Toll-like receptors and stimulate cytokine production. *(From Schrijver IA, Melief MJ, Tak PP, et al: Antigen-presenting cells containing bacterial peptidoglycan in synovial tissues of rheumatoid arthritis patients coexpress costimulatory molecules and cytokines.* Arthritis Rheum *43:2160, 2000.)*

Bacterial peptidoglycans are also abundant in RA synovial tissue (Figure 69-5). Antigen-presenting cells containing these products express TLRs that can be ligated and produce pro-inflammatory cytokines. The peptidoglycans could either activate cells in situ, or phagocytic cells from other sites or the blood could engage the molecules and then migrate to the joint. In either case, it is not difficult to imagine how they can contribute to synovial inflammation.

Several animal models of arthritis are dependent on TLR2, TLR3, TLR4, or TLR9. For instance, rodents injected with streptococcal cell walls (TLR2 ligand) develop severe polyarticular arthritis. The initial phase of disease resolves and is then followed by a chronic T cell–dependent phase that resembles RA. The arthritogenicity of complete Freund's adjuvant in the rat adjuvant arthritis model is dependent on mycobacterial DNA that binds to TLR9 and activates an adaptive immunity. Endogenous TLR4 ligands such as HSPs and fibrinogen also play a role in immune complex models such as passive K/BxN arthritis.[47]

Mycoplasma-derived superantigens such as from *Mycoplasma arthritidis* can directly induce T cell–independent cytokine production by macrophages and exacerbate or trigger arthritis in mice immunized with type II collagen. Despite circumstantial evidence, most efforts to identify *Mycoplasma* and *Chlamydia* organisms or DNA in joint samples have been negative, and no direct evidence exists to support these organisms as etiologic agents.

### Epstein-Barr Virus, dnaJ Proteins, and Molecular Mimicry

EBV is a polyclonal B lymphocyte activator that increases the production of RF. Rheumatoid macrophages and T cells have defective suppression of EBV-induced proliferation of human B cells. Patients with rheumatoid disease have higher levels of EBV shedding in throat washings, an increased number of virus-infected B cells in the circulating blood, higher levels of antibodies to normal and citrullinated EBV antigens, and abnormal EBV-specific cytotoxic T cell responsiveness compared with control subjects. $CD25^+$ B cells from patients with RA respond more briskly to EBV than do those from normal persons, with increased polyclonal IgG and IgM production.[48] Defective elimination of EBV-transformed lymphocytes in RA has fueled speculation that immune dysfunction contributes to initiation of disease.

Additional intriguing data implicating EBV in RA are derived from sequence homology between the susceptibility cassette in HLA-DR proteins and the EBV glycoprotein gp110. Like DRB*0401, gp110 contains the QKRAA motif, and patients with serologic evidence of a previous EBV infection have antibodies against this epitope. Hence T cell recognition of EBV epitopes in some patients with the SE might elicit an immune response directed at innocent bystander cells through "molecular mimicry." This hypothesis could account for disease perpetuation in the absence of active infection in patients with a specific MHC genotype. RA T cells, especially synovial fluid T cells, have increased proliferative responses to gp110, perhaps supporting the molecular-mimicry link between a variety of QKRAA-containing proteins and arthritis. gp110 is only one of many xenoproteins such as the *Escherichia coli* HSP dnaJ containing QKRAA, so this might be a general phenomenon. Of particular interest, responses directed against dnaJ protein also recognize human Hsp40 proteins DnaJA1 and DnaJ2. Therefore, molecular mimicry is not limited to HLA-DR and can involve other cellular proteins.[49]

### Parvovirus

Parvovirus B19 infection has been implicated in some patients with RA based on serologic evidence, including the nonstructural protein NS1. Only about 5% of patients have evidence of recently acquired parvovirus B19 infection at the time of disease onset. Of interest, 75% of RA synovium samples contain B19 DNA compared with about 20% of non-RA control subjects. Immunohistochemical evidence of the B19 protein VP-1 was detected in patients with RA but not in patients with other forms of arthritis. However, evidence of the B19 genome in RA joint samples was not found in other studies.

The mechanisms of B19-induced synovitis, when it does occur, could also involve alterations in FLS function.[50] In a cell-culture model of synoviocyte invasion into cartilage,

infection with the parvovirus significantly increased the migration of cells into the matrix. Mice that are transgenic for the B19 protein NS1 were more susceptible to collagen-induced arthritis and developed high titers of anti–type II collagen antibodies. These data suggest that the B19 genome might not cause arthritis but can enhance an arthritogenic response to other environmental stimuli. This phenomenon could result from B19-induced apoptosis, where NS1 can form adducts with various products in the apoptotic bodies. These alterations create neoepitopes involving DNA, histone H4, and other proteins that can become immunogenic and enhance autoreactivity.[51]

### Other Viruses

Because rubella virus and the rubella vaccine can cause arthritis in humans, the virus has attracted some attention as a possible triggering agent. Live rubella virus can be isolated from the synovial fluid of some patients with chronic inflammatory oligoarthritis or polyarthritis without clinical evidence of rubella. However, most patients with rubella do not have the classic polyarticular involvement and display an oligoarthritis involving large joints. As with B19 infection, it is possible that a small subset of patients with chronic polyarthritis that is called RA actually have direct infection with wild-type or attenuated rubella virus.

Studies of synovial tissue in a variety of inflammatory and non-inflammatory arthropathies have also demonstrated DNA of other viruses such as cytomegalovirus and herpes simplex, but not adenovirus or varicella-zoster. As with bacterial DNA, parvovirus, and EBV, the localization of viral DNA to the inflamed joint is probably related to the migration of inflammatory cells containing the viral genome or other nonspecific mechanisms rather than an active infection.

Retroviral infections could also contribute to the etiology of RA. However, extensive searches for potential agents have not been fruitful. Endogenous retroviruses are abundant in inflamed and normal synovium, and some transcripts are expressed in RA cells. In one study, higher levels of HERV-K10 gag protein from a common endogenous retrovirus were detected more often in RA compared with OA and normal peripheral blood mononuclear cells. Indirect evidence implicates retroviral infection, such as the demonstration of zinc-finger transcription factors in cultured synoviocytes that increase signaling through p38 mitogen-activated protein (MAP) kinase. In addition, the pX domain of one human retrovirus, human T lymphotropic virus-1 (HTLV-1), causes synovitis in transgenic mice, and synoviocytes from patients infected with HTLV-1 have increased cytokine production.

## Autoimmunity

**KEY POINTS**

**Evidence of autoimmunity can be present in RA many years before the onset of clinical arthritis.**

**Antibodies such as ACPAs and RFs are commonly associated with RA.**

**Autoantibodies in RA can recognize either joint antigens such as type II collagen or systemic antigens such as glucose phosphate isomerase.**

**These autoantibodies can potentially contribute to synovial inflammation through several mechanisms, including local activation of complement.**

The idea that aberrant immune responses are directed toward self-antigens in RA was recognized with the discovery of RF in the blood of patients with the disease. Initially described by Waaler and later by Rose, it was not until the mid 1950s that Kunkel and colleagues firmly established that RF is an autoantibody. ACPAs have largely supplanted RFs as the most sensitive and specific antibody associated with RA. They reflect the underlying immune dysregulation in RA and, in addition to being a biomarker of disease, can also play an important role in the pathogenesis of inflammation in the joint and perhaps even in mucosal sites.

### Anti-citrullinated Protein Antibodies

One of the most striking observations related to autoantibodies is the observation that immunoglobulins that bind to citrullinated proteins are produced by patients with RA and have significant prognostic implications. The discovery originated with reports in the 1970s that antibodies directed against keratin were detected in rheumatoid serum and that the primary target antigen was filament-aggregating protein, filaggrin. These antibodies actually bind to epitopes on filaggrin that contain citrulline, which is derived from post-translational modification of arginine by PADI. Humans have four isoforms of PADI. PADI2 and PADI4 are especially abundant in synovium,[52] and, as previously noted, certain SNPs are associated with RA. The function of PADIs in normal immune responses is not certain, citrullination of some chemokines can decrease their chemoattractant properties, and modification of histones can regulate gene expression in stressed cells.

Induction of *PADI* expression and citrullination of peptides are not specific to RA and can occur in many inflammatory settings.[53] Not only are other inflammatory arthropathies marked by citrullinated proteins, but other organs such as the lungs in smokers have significant *PADI* activity. The presence of citrullinated proteins (CPs) in the lungs of smokers or in other mucosal sites could provide the antigen exposure that can contribute to anti-CP antibody production and begin the long road to the development of RA. CPs are also present in most animal models of arthritis. Immunohistochemistry demonstrates CPs in RA synovial tissue infiltrating cells (Figure 69-6), as well as in extracellular deposits that often co-localize with various isoforms of *PADI*, especially *PADI2* and *PADI4*. Moreover, ACPAs are produced by the rheumatoid synovium, especially tissues with lymphoid aggregates.

The specific proteins that are modified vary widely but include many normal constituents such as fibrinogen, vimentin, and fibronectin, as well as xenoproteins such as EBV-derived peptides.[54] The pattern of protein citrullination or the specificity of antibodies to particular proteins does not thus far have predictive value for developing RA or the severity of disease. One interesting subset involves

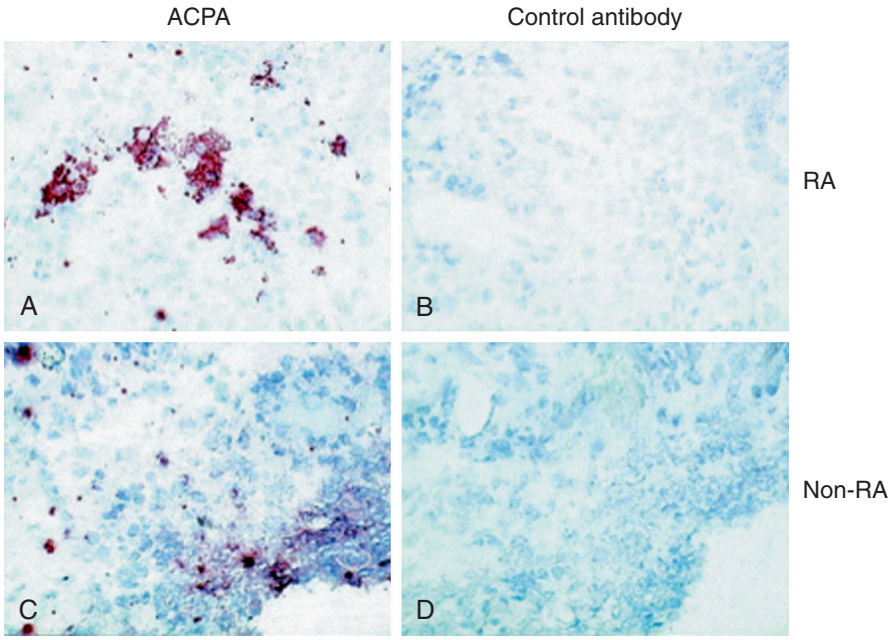

**Figure 69-6** **A** to **D,** Citrullinated proteins in inflamed synovium. Both rheumatoid arthritis (RA) and nonrheumatoid synovium contain citrullinated proteins, detected with an anti-citrullinated protein antibody (ACPA) (*red-brown* in synovium). Control is an irrelevant antibody. Although citrullinated proteins are not specific, the production of ACPAs is more specific to rheumatoid arthritis. *(From Vossenaar ER, Smeets TJ, Kraan MC, et al: The presence of citrullinated proteins is not specific for rheumatoid synovial tissue.* Arthritis Rheum *50:3485, 2004.)*

antibodies that recognize mutant citrullinated vimentin (MCV). These antigens have two modifications that render them more immunogenic: First, there are amino acid changes in the primary sequence such as glycine to arginine. Second, either the new amino acid or another arginine on the protein is citrullinated.[55] The mechanism of amino acid changes has not been defined but could be due to oxidative stress that causes mutations in the genes encoding the protein. These anti-MCV antibodies might be more specific for RA in established disease and more predictive for radiographic progression than other ACPA tests.[56]

ACPAs are present in the serum of 80% to 90% of patients with RA who have established disease using conventional assays. They are also more specific than RF for RA with a specificity approaching 90%. When custom-designed arrays are used, however, as many as 10% of patients negative for ACPA have other ACPA specificities.[57] Perhaps most interesting, ACPA, like RF, can appear long before the onset of clinical arthritis and could be a marker for immune hyperreactivity and subclinical inflammation, leading to protein citrullination in a variety of tissues (Figure 69-7).[58] The more peptides recognized by the repertoire of ACPAs, such as to vimentin, enolase, or various fragments of fibronectin, the greater the likelihood that RA will develop in a person with arthralgias.[59] It is of interest that elevated serum cytokines also predict the development of RA.[60] A genetic contribution to ACPA production was confirmed in the Native American population, where ACPAs are present in nearly 20% of unaffected first-degree relatives and in more than 10% of more distant relatives.[61] ACPAs are also produced by synovial tissue B cells and can be detected in synovial fluid. However, the fact that ACPAs, like RFs, can be detected years before the onset of arthritis and can be found in some normal relatives of patients with RA indicates that the antibodies alone cannot account for initiation of the disease.

ACPAs are predictors of more aggressive disease marked by bone and cartilage destruction. In fact, some data suggest that the HLA-DR associations in RA are actually due to an association between the SE and ACPA production. This association extends to accelerated atherosclerosis in RA, where ACPA positivity is an independent risk factor for ischemic heart disease. In patients with early undifferentiated inflammatory arthritis, ACPAs are also predictive for persons who will progress to RA.[62]

Despite these caveats, ACPAs have pathogenic potential. For instance, ACPAs can activate the classic and the alternative complement pathways.[63] The antibodies have minimal effect when directly injected into mice, and they enhance the arthritogenic potential of anti–type II collagen antibodies in the collagen-induced arthritis model.[64] Mice immunized with citrullinated fibronectin, but not native fibronectin, can develop inflammatory arthritis.[65] Hence the autoreactivity and autoantibodies are not simply a marker of disease but can participate in the disease process. Citrullination can also increase T cell responses to arthritogenic antigens. For instance, citrullination of albumin leads to the formation of antibodies that also cross-react with the unmodified protein. Citrullinated type II collagen and vimentin are more immunogenic than the native protein, most likely because of increased affinity in the binding groove of HLA-DR proteins that contain the SE.[66] ACPAs can also bind to and enhance the activity of osteoclast precursors, suggesting that they can directly contribute to increased bone damage in ACPA$^+$ patients.[67]

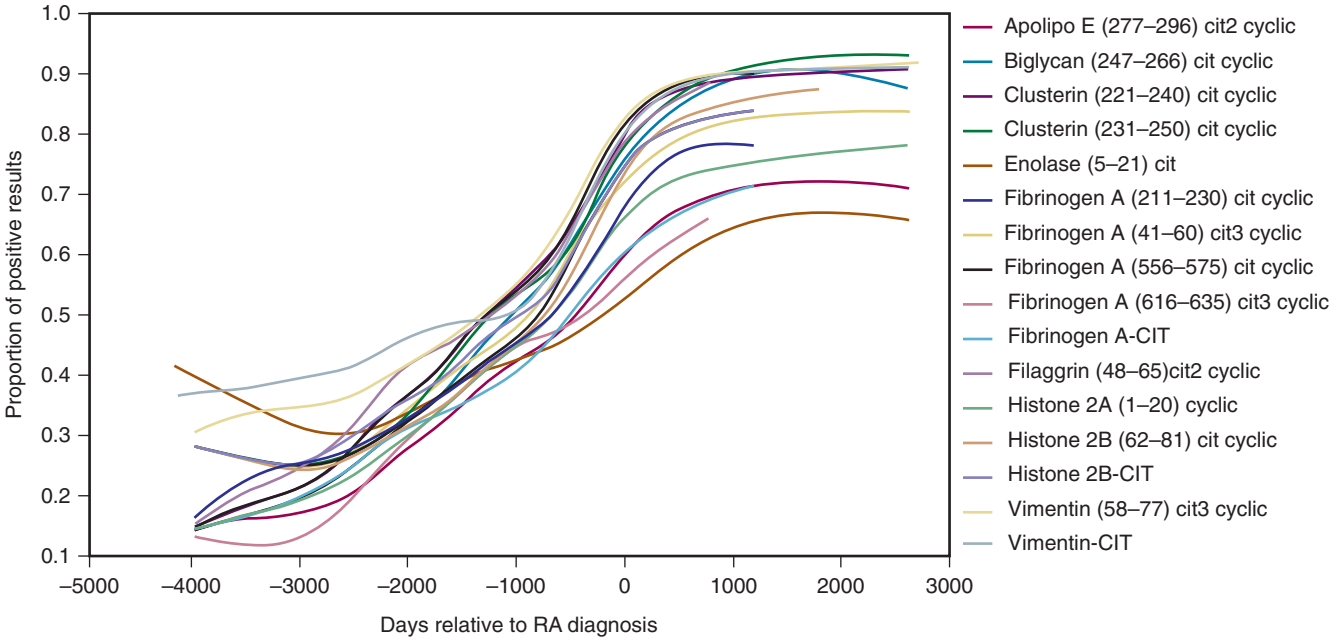

**Figure 69-7** Autoantibody production in rheumatoid arthritis (RA). Anti-citrullinated protein antibodies are detected in the blood long before the onset of clinical arthritis in many patients. Multiple specificities are detected, and all increase at basically the same rate. The levels peak shortly after the onset of symptoms. CIT, Full protein citrullinated in vitro; cit, one citrullinated arginine; cit2, two citrullinated arginines; cit3, three citrullinated arginines; cyclic, peptide is cyclic rather than linear. *(From Sokolove J, Bromberg R, Deane KD, et al: Autoantibody epitope spreading in the pre-clinical phase predicts progression to rheumatoid arthritis.* PLoS One *7:e35296, 2012.)*

### Antibodies to Other Modified Antigens: Anti-carbamylated Peptide Antibodies

ACPAs are the best characterized antibodies directed against modified antigens in RA. However, other antibody systems are also present and could define additional subsets of disease. For example, some patients have antibodies that recognize carbamylated proteins. In this case, lysine is converted to homocitrulline through a non-enzymatic reaction with isocyanic acid and creates neo-epitopes in much the same manner as conversion of arginine to citrulline. Both ACPAs and anti-carbamylated protein antibodies (ACarPs) are present in a subset of patients with RA. More intriguingly, up to 30% of ACPA$^-$ patients have ACarPs, including IgG and IgA antibodies.[68] Like ACPAs, these novel antibodies, such as to carbamylated fibrinogen, can occur before the onset of clinical disease in nearly 40% of patients with RA.[69] The antibodies can participate in the inflammatory response, and mice immunized with carbamylated peptides can develop erosive arthritis. Like ACPAs, the antibodies alone do not cause synovitis. However, lymphocytes from immunized animals can transfer disease to naïve mice.[70] It is tempting to speculate that carbamylated peptides bind avidly to other HLA-DR molecules and define a specific at-risk population for RA.

### Rheumatoid Factor

The identification and characterization of RF as an autoantibody that binds to the Fc portion of IgG was the first direct evidence that autoimmunity might play a role in RA. Seropositive patients have more severe clinical disease and complications than do seronegative patients, including increased cardiovascular complications, although this outcome might be due to the association of RFs with ACPAs.[71] RF can also activate complement by the classic pathway, and there is clear evidence of local complement production and consumption in the rheumatoid joint. Large quantities of IgG RF and RF-containing complexes are produced by rheumatoid synovial tissue and detected in cartilage. B cell–targeted therapies such as rituximab can deplete peripheral B lymphocytes and modestly decrease titers of RF. This effect does not correlate precisely with clinical responses, and synovial RF production is not significantly changed by B cell depletion. Nevertheless, RF levels often decrease in responders and increase again coincident with clinical relapses.

Three-quarters of patients with RA are seropositive when standard tests for RF are used. First-degree relatives of seropositive patients with RA are frequently seropositive, suggesting a genetic contribution. Although IgG and IgM RFs are the most abundant in RA, IgA and IgE RF have also been detected. IgE RF can potentially complex with aggregated IgG in synovial tissue, and the subsequent complexes could then degranulate synovial mast cells through activation of Fc receptors in the synovium.

The RFs produced in persons with RA differ from those produced by healthy people or from patients with paraproteins. The avidity of RF for the Fc portion of IgG is much greater in RA than in Waldenström's macroglobulinemia or in cryoglobulins. Many RFs expressed by abnormal B cells (such as Waldenström's macroglobulinemia) and by normal B cells in human tonsils are derived from the germline. In contrast, RFs in RA are derived through rearrangements and somatic mutations of the germline genes. RF production can be quite high in rheumatoid synovium; IgM RF represents about 7% of the total IgM and 3% of the total IgG produced by synovial cell cultures.

RFs in RA primarily use the IgG variable heavy 3 *(IGHV3)* gene and a variety of variable light (VL) genes, whereas natural antibodies with RF activity use *IGHV1* or *IGHV4* and the *IGKV3* genes.[72] The κ light chain repertoire expressed in RF-producing cells isolated from one RA patient was enriched for two specific Vκ genes but contained many somatic mutations and non–germline-encoded nucleotides.[73] Therefore, the selection and production of these specific RFs were likely due to antigenic drive rather than derived directly from the germline. Additional RFs have been identified with characteristics similar to an antigen-driven response. A crystal structure of one IgM RF bound to IgG showed a key contact residue of the RF with the Fc portion of IgG containing a somatic mutation, supporting the notion that the mutations are related to affinity maturation.

## Autoimmunity to Cartilage-Specific Antigens

Because synovial tissue inflammation is a hallmark of RA, it is only natural to assume that certain joint-specific antigens might play an etiologic or pathogenic role. The emerging picture of autoimmunity in RA tends to implicate patterns of self-directed responses, rather than a single epitope that encompasses all patients at all times during the disease. It is quite possible that articular autoimmunity could vary with the stage of disease, the clinical manifestations, and treatment.

**Type II Collagen.** The discoveries that immunization with type II collagen can cause arthritis in rodents and that the disease can be passively transferred by IgG fractions containing anti-collagen antibodies or by transfer of lymphocytes from affected animals spawned extensive studies defining the mechanisms of disease, the dependence on class II MHC genes, and the potential relationship with RA. T cells are required for initiation of collagen-induced arthritis, and a major immunogenic and arthritogenic epitope on type II collagen resides in a restricted area of the type II collagen chains. The disease is caused by anti-collagen antibodies that localize to the joint and activate complement.

In contrast, type II collagen antibody generation is probably not the initiating event in RA but can amplify the inflammatory response (Table 69-4). It is very likely that immunoreactivity begins with antibodies that bind to citrullinated type II collagen, with epitope spread to include the unmodified or denatured protein. Of interest, T cell responses to type II collagen, especially a dominant epitope at amino acid 263-270, are much greater if the epitope is glycosylated or if the protein is citrullinated.[74] Sera from patients with RA contain antibody titers to denatured bovine type II collagen that are significantly higher than those found in control sera.[75] Anti-collagen antibodies purified from the sera of patients with RA can activate complement, generating C5a when they bind to cartilage. In addition, isolated synovial tissue B lymphocytes actively secrete anti–type II collagen antibodies in almost all patients with seropositive RA, whereas articular cells from patients who do not have RA do not secrete these antibodies. Synovial fluid T cells also recognize and respond to type II collagen, and 3% to 5% of RA synovial fluid–derived T cell clones are autoreactive to the protein.

**gp39 and Other Cartilage-Specific Antigens.** Several other cartilage components besides type II collagen also elicit immune responses in RA. Among the most provocative is cartilage glycoprotein gp39. Several gp39 peptides can bind to the HLA-DR*0401 molecule and stimulate proliferation of T cells from patients with RA. BALB/c mice, which are often resistant to experimental arthritis, develop polyarticular inflammatory arthritis after immunization with gp39 and complete Freund's adjuvant. Although anti-gp39 antibodies are detected in only a small percentage of patients, detection of these antibodies is relatively specific for RA.[76] Other examples of potential cartilage autoantigens include proteoglycans, aggrecan, cartilage-link protein, and other types of collagen. Proteomic analysis of RA serum using peptide arrays to detect multiple autoantibodies also identifies anti-gp39 antibodies in patients with early RA, which may be associated with less aggressive disease.[76a]

## Autoimmunity to Nonarticular Antigens

Autoimmune responses in RA can also involve antigens that are broadly expressed beyond the joint.[77] These antigen-antibody systems comprise a pattern of autoimmune responses that can potentially lead to synovial inflammation.

## Glucose-6-Phosphoisomerase

Spontaneous inflammatory arthritis develops in K/BxN mice as a result of antigen-specific immunity against a seemingly irrelevant nonarticular antigen.[78] Autoantibodies to the ubiquitous enzyme glucose-6-phosphate isomerase (GPI) cause the disease, and transient synovitis also develops in normal mice injected with the serum of the affected K/BxN mice. Mice immunized with GPI also develop antibodies and then inflammatory arthritis. The passive arthritis model requires the alternate complement pathway, Fc receptors (especially FcRγIII), and mast cells, but not T or B cells. IL-1 is more important than TNF in this model, and the IL-1 knockout mice are almost completely protected from disease. Notably, this effect can be overcome by

administration of a TLR ligand like LPS, which shares a downstream signaling pathway with IL-1. Other cytokines, such as IL-6, and signaling pathways, such as p38 MAP kinase and upstream kinases such as MKK3 and MKK6, are also required for full expression of the disease.

Immunohistochemical studies show that the target protein, GPI, adheres to the surface of cartilage, which permits local antibody binding and complement fixation. Initiation of synovial inflammation requires mast cells that increase vascular permeability and provide access to the synovium and cartilage.[79] The initial phase involving mast cell and vascular permeability is augmented by antibody-mediated complement fixation when serum proteins have access to GPI-decorated cartilage.

Although the model initially appears to be the result of a ubiquitous antigen, the display of GPI on the surface of cartilage suggests that it has much in common with arthritis models caused by "joint-specific" antigens. Although initial data suggested some specificity for RA, anti-GPI antibodies are detected in a relatively small percentage of patients with RA and are not specific for the disease. Nevertheless, it might, along with several other antibody systems, contribute to local complement fixation and inflammation.

**Heterogeneous Nuclear Ribonucleoprotein-A2 and Heavy-Chain Binding Protein.** Several other autoantigens that are expressed in synovium have been characterized in RA, although they are also produced in many other locations. For instance, antibodies directed against the heterogeneous nuclear ribonucleoprotein-A2 (hnRNP-A2), sometimes called RA33, occur in about one-third of patients with RA, as well as patients with other systemic autoimmune diseases. Anti-RA33 antibodies are also produced in the TNF transgenic mouse model of RA, suggesting that pro-inflammatory cytokines can independently lead to a breakdown of tolerance for this particular protein.[80] Of interest, RA33$^+$ patients with early RA (symptoms for less than 3 months) tended to have less destructive disease.[81] Although not especially sensitive or specific for RA when used in isolation, an algorithm involving anti–RNP-A2, RF, and ACPA can be used to predict which patients with early synovitis will progress to erosive RA.[82]

Autoantibodies that bind to stress-protein Ig heavy-chain binding protein (BiP) have also been observed. About 60% of patients with RA have anti-BiP antibodies, and the specificity is reportedly more than 90%. In addition to humoral responses, RA T cells can proliferate in response to this protein.

**Heat Shock Proteins.** The HSPs are a family of mainly medium-sized (60 to 90 kDa) proteins produced by cells of all species in response to stress. Another smaller HSP (HSP27) can serve as substrates for enzymes such as p38 MAP kinase that regulate stress responses. Immunity against HSPs contributes directly to synovitis and joint destruction in the adjuvant arthritis model in rats in which T lymphocytes recognize an epitope of mycobacterial HSP65 (amino acids 180 through 188). Some of these cells also recognize cartilage proteoglycan epitopes, perhaps explaining the targeting of joints.

Some patients with RA have elevated levels of antibodies to mycobacterial HSPs, especially in synovial fluid. The majority of T cell clones isolated from RA synovial fluid with specificity to mycobacterial components express the γδ–TCR and do not display CD4 or CD8 surface antigens. Freshly isolated synovial fluid T cells from patients with RA briskly proliferate in response to recombinant 65 kDa HSP, whereas proliferation to other recall antigens such as tetanus toxoid is not increased. Synovial fluid mononuclear cells activated by 60 kDa mycobacterial HSP inhibit proteoglycan production by human cartilage explants.

## SYNOVIAL DISEASE AND BIOLOGY

**KEY POINTS**

- The synovium in RA is marked by intimal lining hyperplasia and sublining infiltration with mononuclear cells, especially CD4$^+$ T cells, macrophages, and B cells.
- Intimal lining FLS display unusual aggressive features.
- Macrophages in the intimal lining are highly activated and produce many cytokines.
- Lymphocytes can either diffusely infiltrate the sublining or form lymphoid aggregates with germinal centers.
- Sublining CD4$^+$ T cells mainly display the memory cell phenotype.
- Synovial B cells and plasma cells in RA exhibit evidence of antigen-driven maturation and antibody production.
- DCs can potentially present antigens to T cells in synovial germinal centers.
- Mast cells produce small molecule mediators of inflammation and can participate in disease initiation by increasing vascular permeability.
- Neutrophils are rarely present in RA synovium but are usually abundant in synovial effusions.

The primary inflammatory site in RA is the synovium. Infiltration of synovial tissue with mononuclear cells, especially T cells and macrophages, and synovial intimal lining hyperplasia are hallmarks of the disease (Figure 69-8). In this section, the various cell lineages and histologic patterns of rheumatoid synovium are discussed.

### Synovial Intimal Lining Cells: Type A and Type B Synoviocytes

The synovial intimal lining is a loosely organized collection of cells that form an interface between the synovium and the synovial fluid space. The intimal lining cells lack tight junctions and a definite basement membrane. The increase in cell number in RA can be quite substantial. In the normal joint, the lining is only one to two cell layers deep, whereas in RA it is often 4 to 10 cells deep. Two major cell types are found in the lining: a macrophage-like synoviocyte (also known as a type A synoviocyte) and an FLS (also called a type B synoviocyte). The former are derived from the bone marrow and express macrophage surface markers such as CD68, Fc receptors, and CD14, as well as abundant HLA-DR, whereas the latter express little if any class II MHC antigens, are devoid of macrophage markers, and have a scant endoplasmic reticulum. FLS express some proteins that are unusual for mesenchymal cells, including vascular cell adhesion molecule-1 (VCAM-1), CD55 (decay

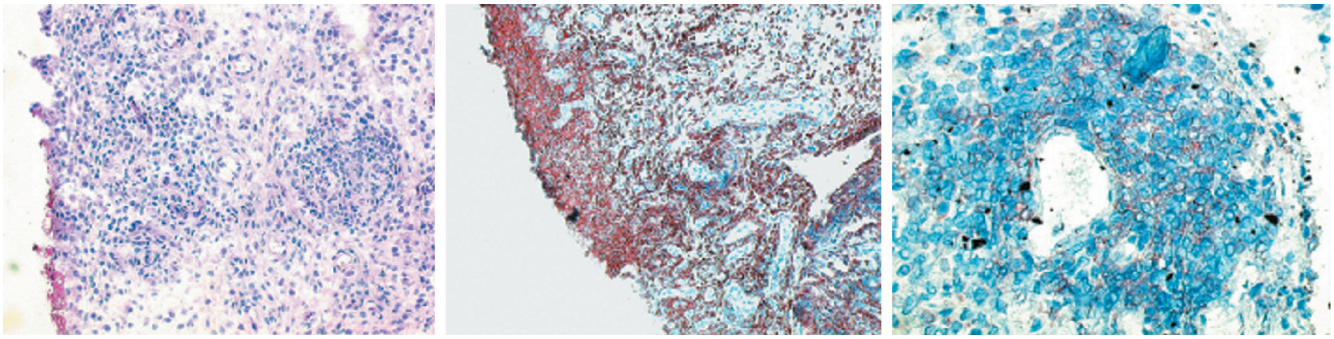

**Figure 69-8** The histopathologic appearance of rheumatoid arthritis synovium. Intimal lining hyperplasia, angiogenesis, and a prominent mononuclear cell infiltrate are present. activating factor), cadherin-11, junctional adhesion molecule C (JAM-C), and the proteoglycan-synthesis enzyme, uridine diphosphoglucose dehydrogenase. The relative numbers of type A and B cells are usually similar in normal synovium. There is an absolute increase in both cell types in RA, although the percentage increase in macrophage-like cells is often greater. In addition, the type A synoviocytes tend to accumulate in the more superficial regions of the intimal lining.

Intimal lining synovial macrophages and sublining macrophages are terminally differentiated cells that presumably do not divide in the joint, and the accumulation of cells in RA is likely from the ingress of new bone marrow–derived precursors. Mesenchymally derived FLS can divide locally in response to the growth factors generated by the activated immune response. Platelet-derived growth factor (PDGF), transforming growth factor (TGF)-β, TNF, and IL-1 produced by many different cells combine with products of arachidonic acid metabolism to induce proliferation of these cells. In addition, pluripotential mesenchymal stem cells that arise in the bone marrow and circulate through the blood can migrate into the synovium and differentiate into type B synoviocytes.[83] Retention of macrophages in the intimal lining is probably due to expression of adhesion molecules such as VCAM-1 and JAM-C on FLS and is likely directed by chemotactic factors produced by FLS. For example, in micromass cultures composed of laminin and FLS, the FLS migrate to the surface of the micromasses and then can recruit macrophages in the interior to the "lining" (Figure 69-9).[84] Formation of this artificial intimal lining is dependent on the adhesion molecule cadherin-11.

Although local proliferation of cells in the intimal lining can occur, mitotic figures in rheumatoid synovium are rare, and thymidine uptake indicating DNA synthesis occurs in only a small percentage of synovial cells. Using a monoclonal antibody that recognizes dividing cells, an even lower rate of cell division (~0.05%) is apparent.[85] A somewhat higher percentage of cells that express the cell cycle–specific antigen proliferating cell nuclear antigen is present in RA lining compared with OA. This finding correlates with the lining cell expression of the proto-oncogene c-Myc, which is intimately linked with fibroblast proliferation.

The architecture of the synovial intimal lining is distinct from other lining layers in the body. In contrast to serosal surfaces, the intimal lining does not include epithelial cells, it lacks a basement membrane, and it has no tight junctions. Rather than serving as a discrete barrier, it is a loose association of cells that is discontinuous in some locations. Cadherin-11, from a class of adhesion proteins that are ubiquitous in various tissues, serves as the major mediator of homotypic aggregation by FLS.[86] Immunohistochemistry shows abundant expression of this protein in the intimal lining. Its importance in the synovial architecture was confirmed in cadherin-11 knockout mice, in which the intimal lining was virtually nonexistent. As previously noted, cadherin-11 mediates self-aggregation of FLS in vitro. Blocking cadherin-11 with antibodies suppresses arthritis in the passive K/BxN model. These data suggest that FLS not only organize the intimal lining formation, but also, like T cells, B cells, and macrophages, play a critical role in the pathogenesis of inflammatory arthritis.

Two major populations of adherent cells can be readily identified when rheumatoid synovium is enzymatically dispersed and cultured in vitro. One type of cell is macrophage-like, which expresses HLA-DR antigens, Fc receptors, and monocyte lineage–differentiation antigens, and is capable of phagocytosis. The macrophages, which constitute about 20% of the total cell number in the rheumatoid joint, can be derived either from the intimal lining or the sublining region. These cells are highly activated in the synovium and produce large amounts of inflammatory mediators, including cytokines and arachidonic acid metabolites.

A second type is defined by the presence of antigens expressed primarily on fibroblasts and by the absence of phagocytic capability, DR antigens, or antigens of the monocytic lineage. When the enzymatically dispersed cells are cultured for several passages, this latter cell type survives and proliferates, resulting in a relatively homogeneous population of fibroblast-like cells. Most published reports of cultured synoviocytes utilize this population of cells.

Fibroblast-like cells grow slowly, with a doubling time of 5 to 7 days, and can be passaged for several months in vitro. Although it has not been proven that these cells originate solely from the synovial intimal lining, the fact that a significant percentage of cells express VCAM-1 and CD55 suggests that at least some are derived from this region. Synovial fibroblasts from RA have been imprinted in vivo, possibly as a result of epigenetic changes like DNA methylation (see Figure 69-3), and exhibit an aggressive phenotype when cultured in vivo or when implanted into mice.

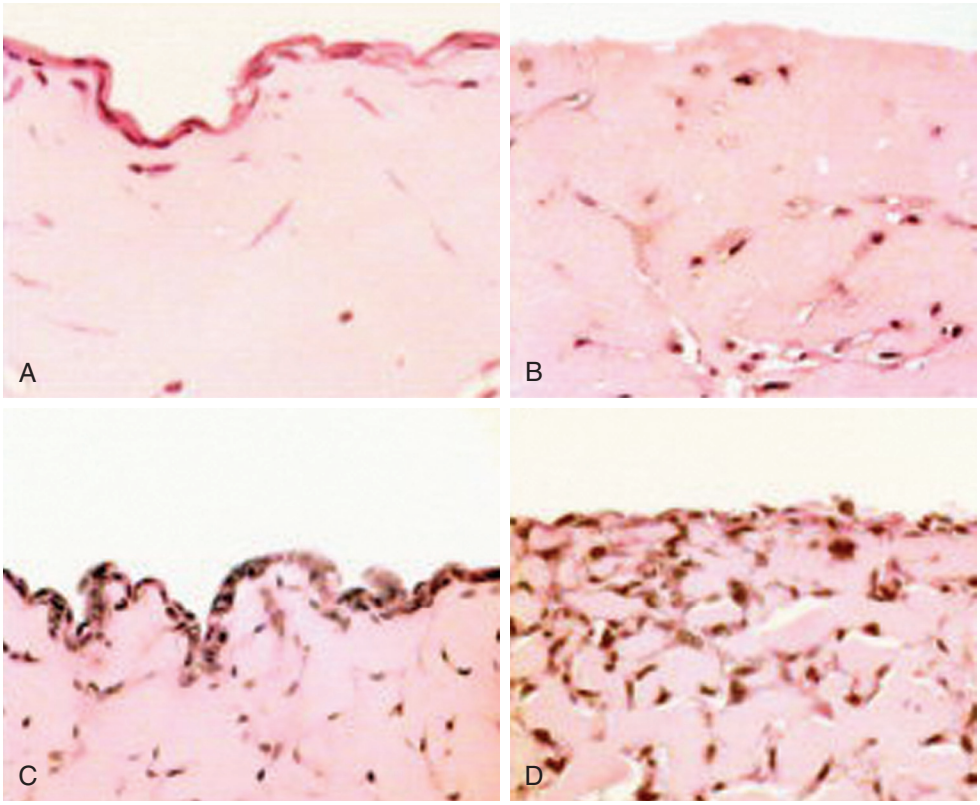

**Figure 69-9** Fibroblast-like synoviocytes (FLS) are programmed to form the synovial intimal lining. Human and mouse FLS spontaneously form lining structures when embedded in a three-dimensional matrix composed of the matrix protein laminin. The cells migrate to the surface of the structure over 3 weeks and resemble an intact synovial lining. The figure shows parallel experiments using human **(A)** and mouse **(C)** fibroblast-like synoviocytes. Of interest, dermal fibroblasts from human **(B)** or mouse **(D)** skin do not migrate to the surface, indicating that the synoviocytes are preprogrammed for this function and that it is not a property of all fibroblasts. *(From Kiener HP, Watts GF, Cui Y, et al: Synovial fibroblasts self-direct multicellular lining architecture and synthetic function in three-dimensional organ culture.* Arthritis Rheum *62:742, 2010.)*

Experiments examining synovial tissue and FLS gene expression profiles suggest that specific patterns correlate with synovial histopathology.[87] FLS from highly inflamed synovium exhibited a TGF-β gene signature that has also been described in cells with features of both smooth muscle cells and fibroblasts that are found in many mucosal surfaces known as *myofibroblasts*. A second pattern observed in cells derived from relatively non-inflammatory RA tissue had increased expression of insulin-like growth factor–regulated genes. Attempts to distinguish RA and OA FLS expression profiles have offered mixed results, but some differences have been observed using microarray technology. Using a systems biology to analyze the transcriptome, a network of invasive processes could be established that includes twist basic helix-loop-helix transcription factor 1 (TWIST1) and periostin (which regulates integrin-mediated cell migration) as key differentially expressed genes.[88] These networks, which have also been explored in FLS epigenetic signatures, can potentially identify unanticipated therapeutic targets.

## Aggressive Behavior of RA Fibroblast-like Synoviocytes

**Tumor-like Properties.** Rheumatoid FLS demonstrate some aggressive properties compared with cells obtained from other synovia or tissues. For instance, adherence to plastic or extra-cellular matrix is generally required for normal fibroblasts to proliferate and survive in culture. Although FLS typically grow and thrive under conditions that permit adherence, RA synoviocytes can also proliferate in an anchorage-independent manner.[89] In addition, cultured RA synoviocytes can exhibit defective contact inhibition and express proto-oncogenes, such as c-Myc, that are typically abundant in tumor cells. Poorly regulated cell growth likely occurs in vivo as well, and studies examining X-linked genes demonstrate oligoclonality in the synoviocyte population from RA, but not OA, synovium.[90] Oligoclonality is especially prominent in cells derived from the invading pannus, which is the most aggressive region of the synovium. Increased telomerase activity, another feature of transformed tissue, is also present in RA synovium and can be observed in fibroblast growth factor (FGF)–stimulated RA synoviocytes. Epigenetic analysis suggests that overexpression of certain miRNAs or differential DNA methylation is associated with increased cytokine production or more aggressive behavior.

**Matrix Invasion.** The most compelling evidence suggesting that RA synoviocytes are permanently altered is derived from studies in a severe combined immunodeficiency (SCID) mouse model in which synoviocytes and cartilage are co-implanted. The rheumatoid cells adhere to and invade into the cartilage matrix, unlike OA and skin fibroblasts[91] (Figure 69-10). Because these synoviocytes are devoid of T cells and macrophages, there is no contribution from an immune response to murine antigens. The invading

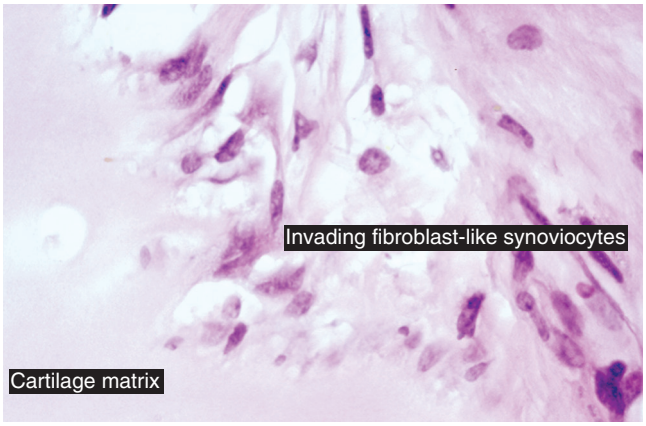

**Figure 69-10** Invasion of rheumatoid arthritis (RA) synoviocytes into cartilage explants in severe combined immunodeficiency syndrome (SCID) mice. RA fibroblast-like synoviocytes were co-implanted with normal human cartilage into the renal capsule of SCID mice. Note that the synoviocytes attached to the cartilage and invaded into the matrix. Several chondrocytes in lacunae are also present. *(Courtesy Dr. S. Gay.)*

cells express VCAM-1, which could facilitate adhesion to cartilage or chondrocytes, as well as proteases that digest the cartilage matrix. If explants are introduced into two locations in the SCID mice, the rheumatoid FLS can migrate from one site to another, presumably via lymphatics and the bloodstream.[92] This finding raises the intriguing possibility that imprinted, aggressive cells can "metastasize" from joint to joint and contribute to the polyarticular nature of RA.

Blocking IL-1 function in the SCID model with IL-1 receptor antagonist (IL-1Ra), a natural antagonist to IL-1, has no effect on synoviocyte invasion but decreases perichondrocyte matrix loss. In contrast, IL-10 or blocking membrane type I MMP, Ras, or c-Myc expression decreases invasion. Surprisingly, overexpression of soluble TNF receptors has little effect in this model. These studies suggest that excessive production of IL-1 and underexpression of IL-10 contribute to the invasive properties of RA synoviocytes. In another study, transfecting normal synoviocytes with the human papillomavirus gene encoding E6, which inactivates p53, induced the rheumatoid phenotype. RA FLS also have prolonged and exaggerated responses to synovial cytokines. For example, TNF induces higher levels of chemokines and MMPs than do control FLS, perhaps because of prolonged activation of transcription factors like nuclear factor-κB (NF-κB).[93] Overall, these studies paint an interesting picture of RA FLS serving as key effector cells that display unique aggressive properties in inflammatory synovitis.

Various cytokines in the joint enhance FLS migration and invasion into matrix, most notably PDGF. The signaling molecules that regulate this process could represent interesting therapeutic targets. Phosphoinositide 3 kinases (PI3Ks) are especially important. FLS express three isoforms (α, β, and δ); α is expressed by many cell lineages, but δ is usually restricted to bone marrow–derived cells.[94] The δ isoform is unexpectedly expressed by FLS and is markedly induced by TNF. Functional studies and the use of kinase inhibitors suggest that PI3Kδ is perhaps the most important isoform that regulates cell movement and matrix invasion.

## Synovial T Lymphocytes

### Immunohistologic Patterns

In chronic RA, the synovium contains a collection of T lymphocytes that can lead to an organizational structure that resembles a lymph node. The distribution of lymphocytes in the tissue varies from discrete lymphoid aggregates to diffuse sheets of mononuclear cells, with the most prominent location for T cells being the perivascular region. These collections consist of small, $CD4^+$ memory T cells ($CD45RO^+$) with scant cytoplasm. Scattered $CD8^+$ T cells can accumulate in the aggregates, and overall, substantially more $CD4^+$ cells are present. Peripheral to these foci is a transitional zone with a heterogeneous mixture of cells including lymphocytes, occasional undifferentiated blast cells, plasma cells, and macrophages (see Figure 69-8). Synovial lymphoid aggregates occur in at least 15% to 20% of patients; although originally considered specific for RA, it is now clear that they are equally prevalent in psoriatic arthritis and are even seen in some people with OA.[95] The presence of aggregates correlated with higher production of ACPAs and RF in synovium, but not with clinical disease activity.

Considerable heterogeneity exists in the histologic patterns from patient to patient and within a single joint. Synovial biopsy studies suggest that at least six sites must be evaluated to decrease the risk of sampling error to 10% to 20% or less. In situations in which the synovial tissue of more than one joint from an individual patient is available, the same general histopathologic patterns are usually apparent in tissue from separate sites.

**Regulation of T Cell Aggregate Formation.** T cells often constitute 30% to 50% of cells in RA synovia, and most are $CD4^+$. About 5% of cells are B lymphocytes or plasma cells, although in some tissues the percentage can be considerably higher. The B cells are located primarily within reactive lymphoid centers, whereas plasma cells and macrophages are often found outside these centers. This arrangement is consistent with T cell–dependent B lymphocyte activation. Plasma cells, the main immunoglobulin producers, migrate away from the germinal centers after differentiation. CD4 cells in RA synovium are in intimate contact with B lymphocytes, macrophages, and DCs.

Aggregate formation is complex and involves numerous signals to orchestrate the organization of individual cell lineages. In some cases, follicular DCs are present and are involved in forming true germinal centers (discussed in a subsequent section). The presence or absence of aggregates and germinal centers is a dynamic process. In one study evaluating synovial biopsies, the presence of lymphoid neogenesis was not restricted to patients with autoantibodies. Even though the cytokine and chemokine profile supports the formation of these structures, progression to fully differentiated follicles was uncommon.[96]

Chemokines play a central role in the organization of tissues into lymphoid structures such as aggregates and germinal centers. CXCL13 and CCL21 are especially important, and their expression in rheumatoid synovium correlates with the presence of this microarchitecture.[97] The former, in particular, is produced by synovial follicular DCs. Similarly, plasma cells expressing the chemokine receptor

CXCR3 are present in the rheumatoid synovium. The CXCR3 ligand, Mig/CXCL9, is highly expressed by intimal lining synoviocytes and sublining cells and recruits these cells to the T cell aggregates.[98]

The architecture of lymphoid structures in rheumatoid synovium is also regulated by members of the TNF superfamily. Lymphotoxin-α and -β (LTα and LTβ, respectively), as well as lymphotoxin-related inducible ligand that competes for glycoprotein D binding to herpesvirus entry mediator on T cells (LIGHT), form trimeric molecules in various combinations that can bind to distinct cell surfaces. These three cytokines regulate the function and organization of lymphoid tissues. Deletion of either LTα or LTβ seriously impairs lymphoid development, whereas lymph nodes develop normally in LIGHT-deficient mice. In the SCID mouse model using RA tissue explants, depletion of $CD8^+$ T cells led to loss of follicular DCs, depletion of LTα1β2, and disintegration of the lymphoid follicles.[99]

Although LTα is difficult to detect in RA, other TNF superfamily members such as LTβ, TWEAK (TNF-like weak inducer of apoptosis), and LIGHT are present.[100] In addition to regulating lymphoid aggregate and germinal center formation, LT can also directly stimulate FLS to produce chemokines such as CCL2 and CCL5 that attract T cells into the joint. LIGHT also enhances osteoclast differentiation and induces expression of MMP-9, TNF, IL-6, and IL-8 by macrophages. LTβ and LIGHT blockade using soluble receptors decreases the severity of collagen-induced arthritis.[101] However, the inhibitor was not effective in the passive arthritis model in which the pathogenic antibodies were directly administered to mice. Hence the LIGHT axis has a more important role in the early phases of disease when adaptive immunity to joint antigens is developing. TWEAK can also play a role in Th17 differentiation, and its inhibition suppresses disease severity in collagen-induced arthritis.[102]

### Synovial T Cell Phenotype

**Co-stimulatory Molecules.** RA synovial T lymphocytes exhibit an activated surface phenotype, with high expression of HLA-DR, CD69, and CD27. The co-stimulatory molecule CD28 is highly expressed by synovial T cells in RA. Its ligands, CD80 and CD86, are also displayed on antigen-presenting cells in the joint, thereby providing an excellent environment for T cell activation. The importance of the CD80/86-CD28 interaction is supported by the observation that abatacept blocks CD80/86 and is effective in RA. Other co-stimulatory molecule pairs such as CD40L on T cells and CD40 on antigen-presenting cells are also expressed in RA synovium.

**Adhesion Molecules.** Synovial lymphocytes also express adhesion molecules of the very late activation antigen (VLA) and lymphocyte function–associated antigen (LFA) superfamily of integrins, as well as help recruit and retain lymphocytes to the synovium. The cytokine milieu of the joint induces adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), VCAM-1, and connecting segment-1 (CS-1) fibronectin on vascular endothelium. These, in conjunction with chemokines and other chemoattractants, attract cells that express the correct adhesion molecule counter-receptors on their surface.

**Chemokine Receptors.** Synovial T cells in RA express characteristic receptors to specific chemokines. The chemokine receptor CCR5 is the ligand for macrophage inhibitory proteins 1α and 1β and is highly expressed in the infiltrating RA T cells. This particular receptor, along with CXCR3, is preferentially found on Th1 cells, an observation that might explain accumulation of this phenotype in the rheumatoid synovium. In fact, expression of nonfunctional CCR5 alleles that protect from HIV infection might diminish the risk of RA. The chemotactic factor stromal cell–derived factor-1 (SDF-1) is also produced by synovial tissue, and its specific receptor, CXCR4, is displayed by rheumatoid synovial T cells. Other T cell phenotypes recruited to the rheumatoid synovium include Th17 cells that express CCR2 or CCR6 and produce IL-17 and $CD4^+CD25^+$ regulatory T (Treg) cells that can suppress immune responses (see the subsequent discussion of T cell subsets). Preferential recruitment of $CCR6^+$ Th17 cells into the rheumatoid joint appears to be due to the local release of the chemokine CCL20.[103]

**T Cell Receptor Rearrangements.** In some patients, a pattern emerged suggesting an increased number of T cells expressing Vβ3, Vβ14, and Vβ17, especially in synovial tissue. These Vβ genes are structurally related and are unusually susceptible to activation by superantigens. Most studies have not found evidence for the restricted clonality of T cells in RA synovial fluid, synovial tissue, and blood or identified expansion of different Vβ or Vα genes.

**Determinants of T Cell Phenotype.** The local accumulation of T cells in the joint is not always related to proliferation induced by a particular antigen. Instead, antigen-independent processes related to the expression of chemokines and adhesion molecules on vascular endothelium and circulating lymphocytes help determine the mononuclear cell infiltrate. Although local antigen-specific expansion can occur, it is probably responsible for a relatively small percentage of the T cell infiltrate. Cells that encounter their appropriate antigen in the correct cytokine and antigen-presenting cell environment can potentially activate other local cells through direct cell-cell contact or the elaboration of lymphokines. A high level of telomerase activity is also present in synovial lymphocytes in RA, which is a reflection of their proliferative activity and correlates with the severity of synovial inflammation.[104] An alternative explanation for T cell activation in RA is that antigen presentation mainly occurs in central lymphoid organs. In this scenario, DCs that encounter antigens in the synovium or other sites migrate to lymphatic tissue and then present antigen to naïve T cells. Once activated, these T cells enter the circulation and can migrate to the joint, where they can produce cytokines and activate resident cells.

### Synovial T Cell Immunoreactivity

The histopathologic appearance of RA, with exuberant infiltration of the synovium with T lymphocytes, is characteristic of tissues with chronic antigen-specific responses. However, the synovium can only respond to inflammation in a limited number of ways, and many chronic immune-mediated arthropathies have similar histologic patterns, including lymphoid aggregates in OA. In fact, chronic arthritides that clearly are not mediated by T cells (e.g., chronic tophaceous gout) exhibit many of the same features.

The microheterogeneity of the rheumatoid synovial tissue, with different numbers and proportions of cell lineages in each area, could reflect responses to different antigens in various synovial locations in the synovium. Although synovial T cells in these varied locations display an activated phenotype, proliferative and cytokine responses are usually less than normal peripheral blood cells or even autologous peripheral blood T cells from the same patient. Spontaneous and stimulated cytokine production, including Th1 factors such as IFN-γ and IL-2, are relatively low. Responses directed toward most recall antigens are also deficient, although RA synovial T cells can proliferate briskly to certain HSPs. Th17 cells have been detected in both the blood and synovium, perhaps because of exposure to a cytokine milieu that includes IL-1, IL-6, and/or IL-23 that can promote differentiation toward production of IL-17 family members (especially IL-17A and F).

The mechanisms of decreased responsiveness in the synovial compartment likely include exposure to suppressive factors (e.g., TGF-β or IL-1Ra), abnormal redox potentials that suppress TCR signal transduction, the presence of Tregs, or induction of anergy. Another contributor to local anergy could be the relative lack of the co-stimulatory molecule CD80 on HLA-DR$^+$ FLS, which could induce anergy. This phenomenon has been observed in co-cultures of T cells with synoviocytes.

As noted earlier, modified proteins such as through citrullination provide a rich source of antigenic stimulation, although many different peptides are involved. Animal models also suggest that breakdown of tolerance can be due to a combination of factors early in development. For instance, mutations in ZAP70, which is involved with TCR signaling, can lead to spontaneous T cell–dependent inflammatory arthritis in mice.[105] An abnormal *ZAP70* gene leads to defective positive and negative selection in the thymus and allows autoreactive T cells to escape. As a result, mice produce autoantibodies (e.g., RF and anti-dsDNA) and develop a severe destructive arthritis. The disease can be transferred by thymocytes or peripheral CD4$^+$ T cells into syngeneic mice with a normal *ZAP70* gene. This autoimmune response might be more relevant to antigen spread rather than the initial response to modified proteins that were not present during development.

These studies demonstrate that minor changes in the TCR complex and signaling can alter T cell selection and induce arthritis. The finding is especially relevant in light of the association of a *PTPN22* SNP with RA, because this gene is also involved with TCR signaling. Despite the clear T cell dependence of the model, the cytokines implicated are remarkably similar to autoantibody-dependent models of RA. Therefore the cytokine profile in RA represents a final common pathway for a variety of autoimmune mechanisms. This concept is supported by the diversity of responses to targeted therapies in RA and suggests that RA is not a single disease but instead is a group of mechanistically distinct entities with a shared phenotype.[105a]

## Activation of Synovial Cells by Cell-Cell Contact with T Lymphocytes

Even though T cell activation is relatively modest in rheumatoid synovium, direct cell-cell contact permits these cells to participate in synovial cytokine networks and matrix destruction. Membranes prepared from activated T cells can directly stimulate macrophages and FLS to produce cytokines and MMPs.[106] The membrane constituents that regulate this process vary, depending on the particular culture conditions, but include adhesion molecules such as LFA-1 and membrane-bound TNF. Hence a T cell displaying these proteins can potentially contribute to macrophage and fibroblast activation in an antigen-independent fashion. One of the best-characterized consequences of this pathway is the ability of T cells to enhance synovial macrophage TNF production in a contact-dependent manner after exposure to macrophage-derived IL-15.[107]

Although the traditional paradigm suggests that T cells in the joint drive an antigen-specific response, cell-cell contact influences can be antigen-independent and only require co-localization of memory T cells with synoviocytes or macrophages. Because T cells with a memory phenotype accumulate into the joint because of the release of chemoattractants, there is no requirement for a specific antigen. Instead, activation of innate immunity by nonspecific stimuli permits subsequent ingress of the correct T cell phenotype to engage resident synovial intimal lining cells, sublining fibroblasts, or macrophages. The combination of adaptive immune responses and antigen-independent stimulation could contribute to the diversity of individual responses to targeted therapy and the relative paucity of complete remissions.

### Restoring T Cell Tolerance

Because synovial T cell responses and autoreactivity play a key role in the pathogenesis of RA, one potential therapeutic approach is to restore tolerance. This concept has been somewhat problematic because the underlying defect has not been fully defined and could include abnormal thymic selection, genetic factors that lead to altered immune responses, presentation of abnormal proteins in the context of specific MHC proteins, or inadequate regulatory T cell function. What is clear, however, is that current approaches do not "cure" RA, because cessation of therapy usually leads to a recurrence of disease.

Aggressive treatment of early RA (within the year of clinical disease) with methotrexate and a TNF inhibitor could lead to long-lasting remissions.[108] In some cases, therapy can be withdrawn after 1 year of treatment, and patients do not experience a flare for at least an additional year. The mechanism of prolonged remission despite discontinuing therapy in early disease contrasts with less successful attempts to withdraw therapy in long-standing disease. Additional individualized therapies that enhance Treg function, alter co-stimulation, or delete pathogenic T cells are other ways to restore homeostasis and normal immune function.

## Regulatory T Cells

The role of classically defined inducible Tregs (CD4$^+$CD25$^+$CD127$^+$) in RA remains poorly defined. Deficiency of this subset, which produces IL-10 and TGF-β and regulates other T cells through cell contact, could contribute to autoimmunity. The number of Tregs is generally low

in RA synovium, although some reports suggest that it is similar to OA synovium.[109] Interestingly, the number decreases after intra-articular injection with corticosteroids.[110] Characteristic regulatory cells that express Foxp3 and CD39 can be found in RA lymphoid aggregates, especially adjacent to DCs.[111]

The transcription factor STAT3 can also play a role in defining Treg differentiation in the RA joint. Activated STAT3 is abundant in the rheumatoid synovium and can enhance Th17 differentiation while suppressing production of Tregs, whereas STAT5 appears to have the opposite effect.[112] Thus modulating the balance between STATs in RA T cells, such as through Janus kinase (JAK) inhibition, could change the balance between pathogenic and immunosuppressive lymphocytes. Fms-like tyrosine kinase ligand also appears to regulate Tregs in RA and increase their formation.[113]

Studies of RA peripheral blood generally demonstrate normal numbers of Tregs, although the $CD4^+CD25^+$ subset appears to accumulate in rheumatoid synovial effusions. However, peripheral blood Treg responses in vitro to stimuli such as anti-CD3 and anti-CD28 antibody displayed an anergic phenotype and were unable to suppress T cell or monocyte cytokine production. This abnormality might be reversed when patients are treated with TNF inhbitors.[114]

These data suggest that abnormal Treg function could be secondary to cytokine imbalance in RA rather than a primary event. Treatment can have a significant effect on the number and function of Tregs, which makes evaluation of their role in patient samples difficult to interpret. Nevertheless, enhancing or restoring Treg activity as a therapeutic intervention has the potential to downregulate other T cells and cytokine production.[115]

Enhancing the number or activity of Tregs has been evaluated in animal models of arthritis. Antigen-induced arthritis is exacerbated when $CD4^+CD25^+$ cells are depleted and suppressed when they are passively transferred to affected animals. Treg function is low in some inflammation models.[116] Methotrexate also increases Treg function in collagen-induced arthritis. Administration of neuropeptides such as vasoactive intestinal peptide appears to suppress collagen-induced arthritis by enhancing the Treg function in synovium and lymph nodes. However, it is still difficult to ascribe efficacy of therapeutic agents in RA to increased numbers or function of Treg.

## Synovial B Cells

Synovial B cell and plasma cell hyperreactivity increasingly are viewed as key participants in the perpetuation and initiation phases of RA. This notion has been fueled by the descriptions of novel spontaneous models of arthritis in mice, such as the K/BxN model, in which loss of tolerance leads to autoantibody production, activation of innate immunity, and chronic synovitis. Furthermore, B cell–directed therapies such as anti-CD20 antibody are effective in RA. The rheumatoid synovium contains a relatively small number of B cells (<5% of the total cell population), but they are functionally relevant as producers of ACPAs, RFs, and other antibodies that can form immune complexes and fix complement.

### Cytokine Regulation of Synovial B Cells

Although many rheumatoid synovial tissues exhibit a diffuse infiltration with mononuclear cells, a significant percentage also have discrete lymphoid follicles populated by B cells in the sublining region. Follicular DCs, B cells, plasma cells, and T lymphocytes collect in these aggregates. The germinal centers are highly organized structures in which affinity maturation occurs. B cells are present in the aggregates and express the maturation marker CD20, as well as proliferation antigens such as Ki67. The formation of these structures is dependent on soluble and membrane-bound cytokines, including lymphotoxin. B cells accumulate in lymphoid aggregates in RA synovium under the influence of a variety of chemotactic factors, including CCL21 and CXCL13.

A member of the TNF superfamily of cytokines known as B lymphocyte stimulator (BLyS, also called BAFF) has also been identified as a key molecule that regulates B cell differentiation. BLyS binds to transmembrane activator and CAML interactor (TACI), which is present on both B and T cells. If this system is blocked using recombinant TACI-Ig to absorb the cytokine and a related B cell differentiation factor called "a proliferation-inducing ligand" (APRIL), then the number of B cells is dramatically reduced and antibody production is decreased. The same construct is effective as a therapeutic agent in collagen-induced arthritis, a model that depends on autoantibody production.[117]

BLyS is produced in RA synovium, especially by macrophages. Synovial lining type B synoviocytes also can release BLyS, which can be induced by TNF and IFN-γ in vitro. APRIL is localized mainly to DCs in synovial germinal centers. TACI-Ig, which binds both BLyS and APRIL, disrupts the germinal centers and decreases Ig receptors in SCID mice implanted with rheumatoid synovium.[118] Results of clinical trials neutralizing BLyS have been mixed, suggesting that targeting of this cytokine is not as effective as B cell depletion with anti-CD20 antibody. Although improved benefit might be possible with a biologic agent that blocks both APRIL and BLyS, TACI-Ig markedly decreases serum immunoglobulin concentrations but has limited efficacy in RA.[119]

### Synovial B Cell Maturation

B cells isolated directly from germinal centers of RA synovium demonstrate a heterogeneous pattern of V-gene usage and rearrangement. The majority of VH genes are not mutated, suggesting that they are recent immigrants from the peripheral blood and are activated locally. For RF-producing cells, shared mutations containing an identical sequence throughout the variable domain of immunoglobulins have been identified in synovial tissue.[120] Preferential utilization of a limited number of VH and DH gene segments and marked preference for a DH reading frame encoding particular hydrophilic residues have also been observed, consistent with antigen-related selection and maturation. Analysis of expressed heavy-chain variable domains supports the notion that the B cell response in RA synovium is oligoclonal. Similarly, B cell clones isolated from either RA synovium or bone marrow with "nurselike" cells have limited VH usage.

B cells associated with follicular DCs in the rheumatoid synovium can further differentiate and develop additional mutations, suggesting antigen-driven selection. Plasma cells in other areas of the synovium have distinct rearrangements compared with the B lymphocytes associated with DCs. This finding raises the question of whether the plasma cells arise locally or migrate from the blood. Although plasma cell rearrangements are not always similar to the B cells, groups of plasma cells use similar genes, albeit with distinct mutations. Therefore the plasma cells could derive from synovial B cell clones that mutated and whose progeny proliferate and differentiate.

Maturation and survival of B cells depend on stromal cells and cells with nurselike properties that support lymphocyte maturation in the thymus. The synovium of patients with RA also contains nurselike cells, which can increase expression of CD40 and class II MHC proteins on B cells. B cell survival is supported by this population of cells, whereas autoreactive clones evade deletion and produce autoantibodies. A variety of cytokines including granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-6, and IL-8 are produced by RA nurselike cells, and direct contact with B cells is critical for maximal proliferation and antibody production.

### Role of B Cells in RA: Clinical Improvement after B Cell Depletion

The diversity of responses to targeted therapies suggests that many parallel mechanisms can contribute to RA. As with TNF inhibitors, anti-CD20 antibody (rituximab) demonstrates efficacy in RA in a subset of patients. Response rates are higher in patients with antibody profiles that include RF and ACPA, perhaps in combination with chemokines like CXCL13 that attract B cells to synovium. Increasing levels of CXCL13 also predict the return of B cells in the peripheral circulation and could be a useful biomarker for stratifying patients or planning additional courses of rituximab.[121] On the other hand, higher numbers of plasmablasts, as determined by IgJ expression, in the blood are associated with poor response to B cell depletion by ocrelizumab and rituximab (in about 20% of patients). The depleting antibodies do not affect plasma cells, which lack CD20, and persistent disease could be related to the presence of plasmablasts in the blood or joint.[122]

The precise function of CD20 is not well defined; it is expressed on mature B cells but not on plasma cells. Rituximab causes a rapid and profound depletion of peripheral blood B cells. In mice, anti-CD20 antibody depletes B cells in blood, spleen, lymph nodes, and bone marrow. The few remaining B cells in the spleen were of the B1 but not the B2 phenotype. Peritoneal B cells are only partially depleted, suggesting that some sites are privileged and protect B cells despite adequate drug penetration.

In RA, serial synovial biopsies demonstrate only partial B cell depletion after rituximab therapy despite the virtual absence of peripheral B cells. The clinical responses do not always correlate closely with the extent of synovial depletion, although some patients with the most impressive responses appear to have marked declines in the number of B cells in the post-treatment synovial specimens. Surprisingly, B cell depletion does not consistently decrease autoantibody production or cytokine production in the synovium, nor does a change in ACPA or RF levels predict a clinical response.[123] Longer term biopsy studies suggest that plasma cells are decreased in synovium 24 weeks after the treatment with rituximab and that this outcome correlates with decreased symptoms.

The simplest explanation for B cell contributions to RA lies in their ability to produce autoantibodies and differentiate into long-lived plasma cells. Although an increase in RF or ACPA titer can presage clinical relapse, autoantibody titers do not correlate well with disease activity, and RA-associated antibodies can be detected in persons even after a dramatic response. The synovial biopsy data on synovial autoantibody production also suggest that B cells play a more complex and nuanced role in the disease.

Perhaps more important, B cells are potent antigen-presenting cells that could serve this function either in the inflamed synovium or in central lymphoid organs. In a SCID mouse model using rheumatoid synovial explants, T cell activation, lymphoneogenesis, and cytokine production depend on B cells.[124] In the same model, treatment with TACI-Ig to inhibit APRIL and BLyS decreases synovial inflammation and IFN-γ production in tissues with germinal centers.

B cells can also make an array of cytokines, including LTα, TNF, and IL-6. Although macrophages and synoviocytes might produce greater amounts of pro-inflammatory factors, production by B cells in strategic locations in the joints and elsewhere might help drive synovitis. An interesting $FcRL4^+$ B cell subset is increased in RA and can produce TNF and RANKL. The presence of another subset, namely $CD79a^+$ B cells, correlates with erosive disease in patients with long-standing RA.[125] Alternatively, regulatory B cells, like Tregs, could decrease inflammatory responses in RA through the production of suppressive cytokines such as IL-10 and TGF-β. It is not clear whether B cell selectively depletes B cell subsets, and it is possible that the regulatory B cells could be relatively enriched by either rituximab or perhaps other targeted therapies.

## Dendritic Cells

DCs are potent antigen-presenting cells that populate synovial tissue and synovial effusions of patients with RA. DCs sample the environment, especially at mucosal and skin surfaces; process antigens; and then migrate to a central lymphatic site, where they present the antigens to T cells. An emerging appreciation of DC function in the etiology of RA led to the concept that the cells could be loaded with local modified or autoantigens and mucosal sites and migrate to central lymphoid tissues, where they can participate in the initiation of disease. Later, synovial DCs could present antigens in the joint to elicit a local immune response. DCs are also potent producers of type I IFNs, which has been implicated in numerous autoimmune diseases such as lupus and RA. Moreover, IFN signatures have been noted in the joint and blood of patients with RA.

Rheumatoid synovium could function like lymphoid tissues, with mature DCs expressing CD86, CD83, and DC-LAMP localized in perivascular lymphocytic infiltrates and aggregates. Ultrastructural analysis of the synovium shows the DCs in contact with lymphocytes, where they

can present antigens. The presence of DCs is not unique to RA and has been identified in other inflammatory arthritides, including gout and spondyloarthropathies.

Like other immunocompetent cells, DCs are recruited to synovium through the generation of chemotactic factors and expression of the appropriate adhesion molecules. The subsequent localization with the synovium and the formation of microarchitecture such as lymphoid aggregates also depends on production of chemokines in the synovial environment. DCs express the chemokine receptor CCR7, which usually permits them to migrate to lymphoid tissue and orchestrate organization into the appropriate germinal centers. Synoviocytes in RA express two CCR7 ligands (CCL19 and CCL21), which provide a signal for the DCs to remain in the peripheral tissue. Immature DCs and plasmacytoid DCs are also scattered throughout the synovial sublining region. B cell–enriched lymphoid follicles, which are usually organized around follicular DCs (FDCs), are also found in some RA joint tissues. Cultured FLS can perform FDC functions in vitro and could contribute in vivo as well. Synoviocytes derived from patients with RA can bind to germinal-center B cells and suppress B cell apoptosis.

FDC-containing ectopic lymphoid structures in rheumatoid synovium also express high levels of activation-induced cytosine deaminase, a gene that participates in Ig class switching. $ACPA^+$ plasma cells surround these aggregates, suggesting that the aggregates play a role in autoantibody production. The architecture and $ACPA^+$ cells persist when tissue is transplanted into SCID mice. Therefore synovial DCs not only help organize the microarchitecture of synovial tissue but also participate in the development of high-affinity IgG autoantibodies.[126] Aside from presenting antigens, DCs produce cytokines that can influence T cell differentiation in the joint, including IL-12 and IL-23, which can enhance the bias toward the Th1 and Th17 phenotypes (addressed in the following text); APRIL, which enhances B cell survival; and, as previously noted, type I IFNs.

Cytokines in the rheumatoid synovium such as GM-CSF influence the proliferation and maturation of DCs. Increased numbers are found in the tissue and synovial effusions, where they constitute up to 5% of mononuclear cells. RA synovial tissue DCs do not always behave normally. For example, IL-10 suppresses DC function, in part by decreasing expression of CD86 and class II MHC molecules.[127] Synovial FDCs, along with macrophages and FLS, also express the receptor for macrophage colony-stimulating factor (M-CSF, also called CSF-1). Blocking this receptor with a monoclonal antibody suppresses adaptive immunity and collagen-induced arthritis but not a passive serum transfer model, suggesting that the benefit could be a result of suppressing antigen presentation by FDCs.[128]

## Mast Cells, Polymorphonuclear Leukocytes, and Natural Killer Cells

Mast cells are present in the synovial membranes of patients with RA and, in some patients, are located at sites of cartilage erosion. Rheumatoid synovial membranes contain more than 10 times as many mast cells than control synovial samples from patients undergoing surgery for meniscectomy. Mast cells and histamine are also found in a majority of synovial fluid specimens from inflammatory synovitis. A strong correlation exists between the number of mast cells in synovial tissue and the degree of lymphocyte infiltration.[129] Mast cells from RA synovium express significantly higher amounts of the C5a receptor compared with OA synovium.

Resident mast cells in synovium respond to cytokines that stimulate mast cell growth and chemotaxis. Extracts of mast cells can induce adherent rheumatoid synovial cells to increase production of prostaglandin $E_2$ ($PGE_2$) and collagenase, and immunostaining of RA synovial mast cells demonstrates tryptase and TNF. Mast cell–derived heparin has significant effects on connective tissue. In particular, it can modulate the effects of hormones on osseous cells and thereby alter the balance of bone synthesis toward degradation. Synovial mast cells also express Fcε receptors, as well as Fcγ receptor type I and II, but not type III. Immune complexes that ligate type I receptors release $PGD_2$ and TNF, whereas type II receptor ligation releases histamine.[130]

Mast cells have been implicated in the initiation of inflammation in the passive K/BxN model.[131] More recent studies, however, suggest that mast cells might not be contribute as much as originally thought.[131a] The role of mast cells in established disease is also uncertain, and the production of leukotriene $B_4$ ($LTB_4$) in the same model requires neutrophils but not mast cells. However, treatment of synovial tissue explants cultures with a c-Kit tyrosine kinase inhibitor that blocks stem cell factor signaling and decreased production of TNF.[132] These data suggest that mast cells might contribute to synovial cytokines in established disease.

More intriguing, pre-formed IL-17A is present in granules of synovial mast cells in RA.[133] The conventional view of IL-17 is that it mainly comes from activated T cells. Cultured mast cells release the IL-17 when they are stimulated with TNF or immune complexes. A correlation also exists between the presence of IgE and FcR1ε and mast cell degranulation in rheumatoid synovium. More direct evidence of mast cell involvement in RA comes from an open-label clinical trial using the c-Kit inhibitor masitinib in RA, where evidence of clinical efficacy was observed. c-Kit is a receptor tyrosine kinase that binds to stem cell factor and facilitates mast cell growth and survival.

Neutrophils are common in RA synovial effusions, but very few infiltrate the synovium. The cells are immunologically active and can produce IL-17B and IL-1Ra. Synovial neutrophils also release extra-cellular traps (NETs), which are composed of extruded DNA. These traps can capture bacteria and contribute to host defense. In RA, synovial, synovial fluid, and peripheral blood neutrophil NETosis is increased and can be further enhanced by RA serum (especially $ACPA^+$ serum), IL-17A, and TNF.[134] The resultant extra-cellular DNA includes PADI4 and citrullinated peptides such as vimentin.[135] The NETs can then induce other cytokines, IL-6, IL-8, and chemokines. This process can serve as a powerful feedback loop that can increase release of cytokines and citrullinated proteins that might drive immune complex formation.

Natural killer (NK) cells also have been identified in RA synovium.[136] Cytotoxic NK cells contain large amounts of granzymes, which are serine proteases. One potentially

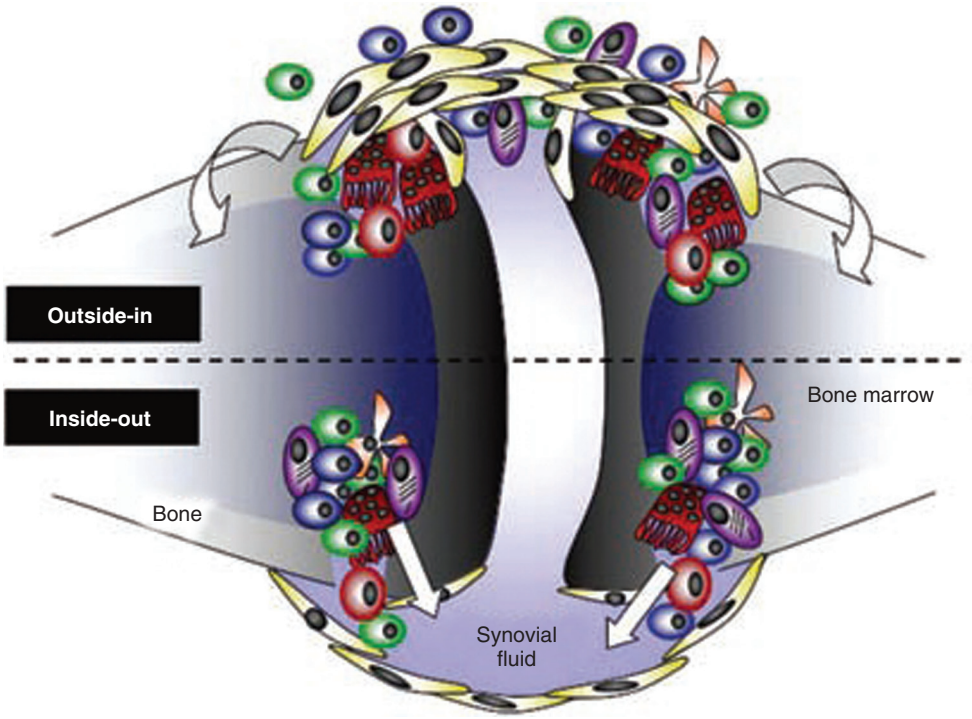

**Figure 69-11** Initial synovial lesion in rheumatoid arthritis (RA). Although traditional paradigms suggest that it begins as a synovial disease, the initial insult could be at a distant site. The figure depicts two possible scenarios: (1) Clinical inflammation in RA begins in the synovium and then extends into the bone and bone marrow, and (2) the initial inflammatory lesion is in the bone marrow, which can extend into the synovium as cells migrate through cortical pores or through the bloodstream. *(From Schett G, Firestein GS: Mr Outside and Mr Inside: classic and alternative views on the pathogenesis of rheumatoid arthritis.* Ann Rheum Dis *69:787, 2010.)*

important immunoregulatory role of NK cells is that they can stimulate B cells to produce RFs. A subset of NK cells that express large amounts of CD56 are unusually abundant in RA synovial tissue and fluid.[137] These cells could potentially produce cytokines or enhance pro-inflammatory cytokine production by T lymphocytes and macrophages. IL-32 exacerbates arthritis and joint damage in collagen-induced arthritis, possibly by increasing the number of synovial NK cells.[138] Little information is available on invariant NK T cells (iNKTs), which respond to lipid antigens. However, blocking CD1d and iNKT function decreases the severity of collagen-induced arthritis in mice.

## Bone Marrow Cells

Although most attention has been directed at the synovium, cartilage, and cortical bone in RA, the subcortical bone and bone marrow also contribute to synovial inflammatory responses. Primitive bone marrow mesenchymal cells can traverse cortical bone through pores in murine collagen-induced arthritis before the onset of clinical disease, take up residence in the synovium, and produce mediators that enhance synovitis.[139] This process is TNF-dependent and is abrogated in mice that lack TNF receptors. $CD34^+$ mesenchymal cells in rheumatoid bone marrow are more highly activated as judged by their NF-κB status and their ability to differentiate into fibroblast-like cells that produce MMPs and proangiogenic factors.

Bone marrow also can contribute other relevant cells, including macrophage lineage cells that migrate to the synovium and nurselike cells that support the survival of B cells. Just as the bone marrow can influence the synovium, the reverse is also true. Invasive pannus can rupture through cortical bone and invade the marrow space in some patients. When this occurs, B cell aggregates are especially prominent in the marrow and occur in an environment rich in B cell chemoattractants such as CCL21 and B cell survival factors such as BLyS.

The bone marrow changes in RA could be either a result of synovitis or a primary event (Figure 69-11).[140] The most common explanation for RA is that synovitis occurs first and that it expands into the marrow through soluble factors and direct extension (the "outside-in" hypothesis). The notion that bone marrow reactivity might be a primary event and that the activated cells migrate directly to the synovium through cortical bone or via the bloodstream has received increasing attention (the "inside-out" hypothesis). The bidirectional interactions between the synovium and the bone marrow suggest that both "inside-out" and "outside-in" mechanisms participate in RA.

## Synovitis in Pre- versus Early-Stage versus Late-Stage Rheumatoid Arthritis

The observation that autoantibody levels are elevated in patients with RA many years before the clinical arthritis manifests also supports the notion that a pre-clinical phase can precede symptomatic synovitis. In addition, profiling of cytokine and chemokine levels in stored serum samples of persons in whom RA ultimately develops shows increased levels of chemokines and cytokines, especially in the $ACPA^+$ population.[141] This finding reinforces the concept that RA

is a continuum that can progress to clinical synovitis. However, the time lines and the environmental stimuli that cause progression are not known.

In murine models, abundant evidence of synovial inflammation and transcription factor activation is present before clinical synovitis is apparent.[142] In contrast, synovial biopsies from "pre-RA" persons with arthralgia but no evidence of arthritis are largely normal, even if they are $ACPA^+$ and/or $RF^+$ and progressed to bona fide RA within 2 years. There was a trend toward higher numbers of $CD8^+$ T cells in the synovium but no other apparent increase in cellular infiltrate or cytokine production.[143]

During the first few weeks of symptomatic RA, the synovium occasionally demonstrates a paucity of lymphocyte infiltration, endothelial cell injury, tissue edema, and neutrophil accumulation; in general, it has a histologic appearance similar to long-standing disease. The extent of lymphoid aggregation, T cell infiltration, and synovial-lining hyperplasia can resemble chronic disease even when symptoms have been present for a short period. The cytokine patterns of these biopsies as determined by immunohistochemical analysis indicated similar levels of T cell factors (such as IFN-γ) and non–T cell factors (such as IL-1 and TNF). The tumor suppressor gene *p53* is also expressed in early-stage RA, most likely as a result of intense oxidative stress in the environment.

Biopsy specimens of asymptomatic joints from patients with early- or late-stage RA also show lymphocyte infiltration, cytokine production, and *p53* expression. Although IFN-γ, IL-1, and TNF levels are increased compared with normal synovium, they are modestly lower than in clinically active joints. Some cytokines such as IL-8 and the number of macrophages are higher in the painful joints. Macrophage and plasma cell infiltration in early RA might predict more erosive or severe disease.

These studies suggest that the transition from being asymptomatic with arthralgia to having synovial inflammation with symptoms in "early" RA, as defined by the duration of symptoms, is rapid. Once symptoms occur, the transition from "early" to "chronic" disease is equally rapid in terms of histology, cytokines, and mechanisms of disease.

## SYNOVIAL FLUID AND THE SYNOVIAL FLUID CARTILAGE INTERFACE

**KEY POINTS**

- **RA synovial effusions contain neutrophils and mononuclear cells, including T lymphocytes and macrophages.**
- **Immune complexes that contain autoantibodies such as RFs or ACPAs can fix complement, leading to the generation of chemoattractants.**
- **Small molecule mediators of inflammation such as prostaglandins and leukotrienes are present in RA synovial fluid.**

Synovial effusions accumulate in the joints of most patients with active RA as a result of a marked increase in fluid influx that cannot be removed despite an increase in lymphatic flow. An inverse relationship exists between the molecular weight of proteins and their concentrations in minimally inflamed synovial fluid. High-molecular-weight serum proteins gain access more easily to synovial fluid in inflamed joints, and the relatively high concentration of IgG in RA synovial fluid is good evidence for local synthesis of immunoglobulins. Markedly increased permeance of proteins in patients with rheumatoid disease is also evidence of the severe microvascular lesion in rheumatoid synovitis. In general, assays for autoantibodies or assessments of exudate versus transudate in synovial fluid have little value; the concentration of serum proteins in effusions is usually about half to two-thirds the level in the blood.

Newer techniques evaluating the synovial fluid proteome in RA using mass spectroscopy might provide new insights into the key mediators. More than 400 proteins in RA effusions were identified as potential biomarkers of disease activity, including C-reactive protein and six members of the S-100 family of calcium granule binding proteins.[144] Additional studies show higher levels of proteins related to complement activation, as well as MMPs and neutrophil-derived proteins. None of these is a particular surprise given the genes expressed by the synovial intimal lining and the abundance of neutrophils in RA fluid. Perhaps more interesting, the "citrullinome" of RA fluids—that is, the pattern of protein citrullination—showed about 3000 different citrullinated peptides, including multiple peptides from vimentin, fibrinogen, and α-enolase.[145] In another study, immune-mediated membranolytic pathways mediated by perforin and the membrane attack complex of complement, both of which are hallmarks of RA effusions, markedly increased citrullination of neutrophils.[146]

### Polymorphonuclear Leukocytes

Large numbers of polymorphonuclear neutrophils (PMNs) accumulate in rheumatoid synovial effusions and enter via postcapillary venules in the synovium. Neutrophils adhere to activate synovial microvasculature as a result of their abundant surface expression of selectins and the β2 integrins. After adherence, chemotactic agents produced by endothelium and resident synovial cells facilitate exit from the intravascular space into the tissue. Thus, considering the survival time of PMNs in synovial fluid, an average rheumatoid effusion containing 25,000 PMNs per $mm^3$ could exceed 1 billion cells each day. The ultimate fate of these cells is usually apoptosis or NETosis with release of DNA and citrullinated peptides. Neutrophil survival requires expression of the forkhead transcription factor gene *FOXO3*.[147] Mice that lack this gene are resistant to inflammatory arthritis because of a shortened PMN life span.

High concentrations of chemotactic agents in the synovial fluid in RA recruit a large number of cells to the intra-articular cavity. Few PMNs are seen in the synovium itself; once in the tissue they move rapidly to the synovial fluid, drawn by agents such as C5a that are generated as a result of complement activation, $LTB_4$, platelet-activating factor, and chemokines. CXC chemokines including ENA-78 and IL-8 are especially abundant in synovial fluid and can attract neutrophils into the intra-articular space. RA PMNs can also release chemokines such as macrophage-inflammatory protein (MIP)-3α into the milieu that promote migration of additional cells into the joint space.

Once in the joint, neutrophils engage immune complexes through Fc receptors, especially FcRγI and FcRγIII,

that activate spleen tyrosine kinase (Syk). This process initiates a signaling cascade that includes the MAP kinases and NF-κB, cytoskeletal reorganization, release of granule content, generation of reactive oxygen and nitrogen species, and enhanced phagocytosis. Many of the cells contain immune complexes within phagosomes that include IgG and IgM along with RF and complement proteins such as C1q, C3, and C4. PMNs from synovial fluid in RA release de novo synthesized proteins including matrix proteins such as fibronectin, neutral proteinases, and IL-1. Neutrophils also secrete IL-1Ra and oncostatin M, which is a member of the IL-6 family. Although the amount of IL-1Ra each neutrophil produces is low compared with macrophages, the sheer number of PMNs allows them to produce large amounts in synovial effusions.

Neutrophil cells also release numerous proteases that can adversely affect the lubricating properties of synovial fluid and the integrity of the cartilage, including elastase and trypsin. Neutrophil collagenase (MMP-8) can digest native collagen in cartilage, which then makes it susceptible to degradation by other MMPs, such as the stromelysins. Synoviocytes are generally considered major producers of the MMPs, but animal models of arthritis suggest that neutrophil-derived proteases also play a significant role in cartilage damage.

Although difficult to assess in humans, animal models demonstrate a role for neutrophils in the inflammatory processes. The passive K/BxN and collagen-induced arthritis models, which depend on autoantibodies to bind to the cartilage and fix complement, require neutrophils for full expression of the disease. Depleting neutrophils with antibodies almost completely prevents synovial inflammation in these models. In the K/BxN model, neutrophils along with mast cells can also initiate the vascular permeability that permits pathogenic antibodies to gain access to the joint space.

## Synovial Fluid Lymphocytes

The lymphocyte subsets in synovial fluid differ from those of peripheral blood and synovial tissue. Even though synovial effusions contain an abundance of T cells, the CD4 to CD8 ratio is actually reversed compared with that of blood or synovial tissue, with an excess of $CD8^+$ cells relative to $CD4^+$ lymphocytes. In addition, synovial tissue is nearly devoid of neutrophils, which often constitute 50% to 75% of synovial fluid cells. The percentage of Tregs ($CD4^+CD25^+$) is also higher in synovial fluid than in peripheral blood.

Synovial fluid contains T cells, which express high levels of surface HLA-DR antigens. Surface activation antigens are increased on synovial fluid lymphocytes, including VLA-1 and CD69. Of $CD4^+$ cells in rheumatoid synovial fluid, most are memory cells and express CD45RO on their surface. Despite the activated phenotype, synovial fluid T cell function is usually deficient compared with peripheral blood cells. For instance, synovial fluid lymphocyte proliferation in response to mitogens or most recall antigens such as tetanus toxoid is significantly less than that of paired blood T lymphocytes. Mycobacterial antigens and the 60 kDa HSP are exceptions because proliferation is actually greater in synovial fluid cells, perhaps because they can also activate TLRs. Cytokine production by synovial fluid T cells in vitro is also low, including mitogen-induced expression of IFN-γ and IL-1.

Defective T cell responses by RA synovial fluid mononuclear cells could be due to anti-inflammatory cytokines such as IL-1Ra and TGF-β.[148] Nonspecific components of joint effusions such as hyaluronic acid can be toxic and indirectly suppress T cell activation. The mechanism of diminished T cell activation also could be due to defective TCR signaling. Articular T cells have diminished tyrosine phosphorylation of proteins after stimulation, especially the key signal transduction pathway p38 MAP kinase. Furthermore, tyrosine phosphorylation of the TCR ζ chain, an early event in TCR signaling, is low compared with peripheral blood T cells. The hyporesponsiveness of synovial fluid T cells correlates with a significant decrease in the levels of the intra-cellular redox-regulating agent glutathione.[149] Restoration of intra-cellular glutathione increases proliferation of RA synovial fluid T cells. Therefore, oxidative stress in the inflamed environment can suppress antigen-specific T cell responses.

## Platelets and Platelet Microparticles

Platelets are a rich source of growth factors and cytokines, including PDGF. They are present in rheumatoid synovial effusions and can form microparticles that contain immune complexes. Some of these particles can display citrullinated peptides such as fibrinogen and vimentin, which can then increase pathogenic innate and adaptive responses.[150] This process is dependent on collagen receptor glycoprotein VI. The microparticles activate cultured synoviocytes and, through an IL-1–dependent mechanism, stimulate cytokine secretion. Platelet depletion also suppresses arthritis severity in animal models.

## Intra-articular Immune Complexes and Complement Fixation

### Synovial Fluid Immune Complexes

Complexes containing Igs are abundant in the blood and synovial fluid of patients with RA, especially those containing IgM and citrullinated proteins. The most prevalent antigens in these aggregates contain IgG bound to RF as a result of their ability to bind the Fc portion of Ig, as well as ACPAs and citrullinated peptide complexes. Use of more sensitive techniques has revealed that circulating immune complexes in RA contain up to 20 polypeptides, including albumin, Ig, complement, type II collagen, fibrinogen, and acute-phase reactants, as well as DNA. These complexes can potentially fix complement, releasing chemotactic peptides and factors that activate neutrophils and other inflammatory cells.

### Immune Complexes Embedded in Cartilage

The aggregates of RF, IgG, ACPAs, and various peptides become embedded into cartilage and other tissues that are in contact with synovial fluids. Electron microscopic studies demonstrate immunoglobulin complexes with damage to the cartilage matrix in the microenvironment. Immune complexes are absent under areas of cartilage invaded

actively by synovial pannus, suggesting that phagocytic cells in the invasive synovium bind to and ingest the immune complexes. Rheumatoid cartilage contains more than 40-fold more IgM and more than 10-fold more IgG than healthy cartilage extracts. IgM RF is found in the majority of RA cartilage extracts but not in OA or healthy control subject extracts. In addition, more than 60% of the RA cartilage extracts are positive for native and denatured type II collagen antibody.

### Synovial Fluid Complement

Biologically active products of complement activation accumulate in synovial fluid during acute inflammation, suggesting a critical role for intra-articular immune complex formation. The liver is the major source of complement synthesis in humans, and passive transfer of serum proteins into effusions accounts for many of the complement proteins found there. However, synovial tissue also actively produces complement proteins. Macrophages and fibroblasts produce complement proteins under the influence of cytokines such as IFN-γ, IL-1, and TNF. Synovial tissue analysis shows that all complement genes from the classic pathway are expressed in RA, as well as in healthy synovium.

Despite the local production of complement components, the activities of C4, C2, and C3 and total hemolytic complement in rheumatoid synovial effusions are lower than in synovial fluids from patients with other joint diseases. Although the most prominent evidence of activation implicates the classic pathway, cleavage products of the alternate pathway, including factor B and properdin, have also been documented in RA. IgM RF appears to be a more important determinant of complement activation than IgG RF in serum and synovial fluid. Accelerated catabolism of C4 in RA and the presence of C4 fragments in the plasma correlate with titers of IgM RF.

The interactions between PMNs and the complement system are considerable. Neutrophil lysosomal lysates contain enzymes that cleave complement proteins and generate chemotactic activity such as C5a from serum. C5a, in addition to being a principal chemotactic factor in inflammatory effusions, mediates lysosomal release from human PMNs and induces cytoskeletal rearrangement. The chemotactic anaphylatoxins C3a and C5a are often present in rheumatoid effusions, as are the terminal complement components that comprise the C5b-C9 membrane attack complex.

### Targeting Complement

Inhibiting complement proteins has clear therapeutic potential in RA. In addition to theoretic considerations and evidence of complement consumption, a polymorphism near the C5 locus has been associated with increased risk of RA. As proof of concept in pre-clinical studies, intra-articular treatment with a soluble complement receptor (sCR1) inhibits joint swelling in rat antigen-induced arthritis. C5-deficient mice have decreased joint inflammation in collagen-induced arthritis and the passive K/BxN model. Absence of C3 or factor B also inhibits collagen-induced arthritis. Unlike the C5 knockout mice, which have normal antibody responses, the C3- and factor B–null animals have lower levels of anti–type II collagen antibodies. The role of C3 convertase has been explored in more detail using transgenic mice that produce the regulatory protein complement receptor 1–related gene/protein y (Crry). These mice have no obvious phenotype and are not more susceptible to infection. However, collagen-induced arthritis is suppressed in Crry transgenic mice.

These data suggest that classic and alternative complement pathways participate in RA. A humanized anti-C5 antibody has been evaluated in a placebo-controlled study. The antibody inhibits C5 activation and function of the C5b-C9 attack complex. Although the monoclonal antibody was well tolerated, only modest evidence of clinical efficacy was found. Similarly, a C5a receptor antagonist did not decrease inflammation in a short-term placebo-controlled synovial biopsy study even though the compound was effective in pre-clinical models and blood levels were in the therapeutic range.[151] C5 alone is not sufficient to sustain inflammation in the rheumatoid joint, and it probably participates in a redundant inflammatory network. It is not clear whether targeting other complement components such as C3 convertase would be more successful.

## Arachidonate Metabolites

### Prostaglandins

Arachidonic acid metabolites are produced in the inflamed joint via oxidation by cyclooxygenases (COX) to prostaglandins and thromboxanes or by lipoxygenases to leukotrienes. COX inhibitors are clearly effective in RA, although the effect is modest and is due to combination of local synovial effects and spinal analgesic action. Animal models of arthritis are variably sensitive to prostaglandin; indomethacin almost completely prevents adjuvant arthritis in rats but has minimal benefit in collagen-induced arthritis in mice. This finding serves as a reminder that results in rodent models do not always correlate with human disease.

Stable prostaglandins, especially $PGE_2$, produce vasodilation, increase vascular permeability, and are involved centrally in fever. They also display some anti-inflammatory activities that could account for limited efficacy. For example, the drug misoprostol, a prostaglandin analogue, has modest but significant anti-inflammatory or immunomodulatory effects. Physiologic concentrations of $PGE_2$ inhibit IFN-γ production by T cells, HLA-DR expression by macrophages, and T cell proliferation.

Production of prostaglandins in RA depends on both COX-1 and COX-2 (see Chapter 24). The former is constitutively expressed and is responsible for the normal endogenous production of prostaglandins in the joint, as well as in other tissues. COX-2, on the other hand, is an inducible enzyme responsible for increased prostaglandin synthesis in inflamed tissue. Cytokines such as IL-1 and TNF induce COX-2 gene expression by cultured synoviocytes and macrophages. COX-2 mRNA and immunoreactive protein are increased in RA synovium.[152] Most nonsteroidal anti-inflammatory drugs, including indomethacin and ibuprofen, inhibit both enzymes. Much of the anti-inflammatory activity and analgesia in RA results from COX-2 inhibition. Targeting prostaglandin receptors such as $E_2$ or $E_4$ is an alternative approach that might have less

deleterious effects on the gastric mucosa and cardiovascular disease. More recent data suggest that PGE receptor 4 (EP4) can also act on DCs and T cells to enhance production of Th1 and Th17 cells.[153]

$PGI_2$, like $PGE_2$, can also contribute to synovial inflammation. For instance, mice lacking the $PGI_2$ receptor have significantly decreased arthritis severity in the collagen-induced arthritis model compared with wild-type mice even though they make similar amounts of anti-collagen antibodies.

### Leukotrienes

LTBs are a potent pro-inflammatory produced by neutrophils and chemotactic for neutrophils, eosinophils, and macrophages. They also promote neutrophil aggregation and adherence to endothelium. Peripheral blood PMNs from patients with rheumatoid disease have an enhanced capacity for $LTB_4$ production compared with normal persons.[154] In murine collagen-induced arthritis, $LTB_4$ antagonists decreased paw swelling and joint destruction, suggesting a pivotal role for this potent chemoattractant. Surprisingly, $LTB_4$ blockade thus far has demonstrated minimal efficacy in RA.

### Anti-inflammatory Arachidonic Acid Metabolites

Certain arachidonic acid metabolites such as 15-deoxy-delta(12,14)-PGJ(2) can bind to peroxisome proliferators, activate peroxisome proliferator-activated receptors (PPARs), and inhibit cytokine production and inflammation in animal models of arthritis. Cyclopentenone prostaglandins can also inhibit NF-κB by blocking one of the key enzymes that activates this pathway, namely IκB kinase-β (IKKβ). Lipoxins and resolvins represent a unique class of lipid mediators that help resolve inflammatory diseases. Lipoxins (LX) have a trihydroxytetraene structure and are produced from arachidonic acid via the lipoxygenase pathways. $LXA_4$ binds with high affinity to a G protein–coupled receptor denoted lipoxin $(LX)A_4$ receptor (ALXR). Activation of ALXR inhibits recruitment of neutrophils by attenuating chemotaxis, adhesion, and transmigration into tissues and by diminishing chemokine and cytokine production. $LXA_4$ significantly decreased cytokine and MMP expression in FLS through an NF-κB–dependent mechanism.

## PERIPHERAL BLOOD LYMPHOCYTES

The number of $CD4^+$ Th cells is mildly increased in the circulation of patients with RA, with a concomitant decrease in $CD8^+$ lymphocytes. The surface phenotype of circulating T cells in RA is highly variable. For instance, an increased percentage of αβ and γδ TCR–bearing cells expressing HLA-DR and the adhesion protein VLA-4 ($\alpha_4\beta_1$ integrin) has been observed. The latter is especially critical in that VLA-4 plays an important role in the recruitment of cells to the synovium through interactions with VCAM-1 on endothelial cells. Other markers of activation are not necessarily elevated on RA T cells in the circulation. Therefore, peripheral-blood T cells express some, but not all, phenotypic characteristics of prior activation. It is not clear whether this process occurs in the peripheral or central lymphoid organs or whether cells are activated in the synovium and re-enter the circulation via the synovial lymphatics.

Immunoregulatory dysfunction has been described in RA peripheral lymphocytes. One early observation was the inadequate control of EBV-infected B lymphocyte growth because of a defect in T cell function in RA. The abnormal T cell response correlates somewhat with disease activity, but the abnormality is present in T cells of some patients with inflammatory arthropathies other than RA.[155] IFN-γ and IL-2 production is significantly suppressed in RA lymphocyte cultures.

T cell diversity and maturation are abnormal in RA. Whereas thymic output normally decreases with age, this process appears to be accelerated in RA.[156] The presence of TCR rearrangement excision circles (TRECs) is a measure of thymic release of mature T cells. Using this parameter, the thymic output in RA may decline prematurely. Similarly, telomere attrition suggests inappropriate "aging" of the T cells. This effect could be due to a primary defect in peripheral T cell homeostasis or impaired thymic function with increased T cell turnover as a result of chronic immune stimulation. This concept is supported by the observation that telomeric length in RA T cells is shorter than in normal control subjects and more closely resembles older populations.

Activated B lymphocytes are also present in the peripheral blood of patients with RA. The number of circulating B cells that spontaneously produce RF and other autoantibodies is significantly higher in persons with RA compared with normal persons. B cells that are enriched in autoantibody production are characterized by a surface determinant CD5. This antigen is normally expressed by T cells but is also displayed by fetal B cells and a small number of immature B cells in adults. Patients with RA who have normal circulating numbers of lymphocytes show an abnormal κ-to-λ–chain analysis compared with control subjects, implying oligoclonal B cell proliferation. As previously noted, plasmablasts are also present in rheumatoid blood, and their presence can be a harbinger of B cell repopulation after treatment with anti-CD20 antibody.

Studies to characterize gene expression profiles in the peripheral blood cells of patients with RA have had mixed results. In some cases, RNA transcripts can potentially distinguish between RA and other forms of inflammatory arthritis and include differential expression of tumor suppressors, MAP kinases, and other pro-inflammatory proteins. Other limited subsets of genes have been proposed as markers for disease activity or to predict response to targeted therapy. However, the patterns are inconsistent, perhaps because blood contains a highly heterogeneous population of cells.

## ROLE OF T CELL CYTOKINES

**KEY POINTS**

**Several T cell subsets have been implicated in the pathogenesis of RA.**

**Relatively low levels of T cell cytokines are present in RA synovium compared with macrophage or fibroblast products.**

**The T cell cytokines that are present, such as IFN-γ and IL-17, can contribute to the pathogenesis of RA and can be produced by Th1 cells or Th17 cells, respectively.**

**Regulatory T cell function, which suppresses activation of other T cells, might be low in RA synovium.**

**T cells can also contribute to synovial inflammation through antigen-independent mechanisms such as direct cell-cell contact with macrophages and synoviocytes.**

The cytokine milieu in RA is rich in factors produced by many cell lineages. Many factors produced by T lymphocytes are surprisingly low in RA, whereas those generated by macrophages and by synovial fibroblasts are markedly increased (Table 69-5). Although low, the T cell cytokines can have profound effects, especially in the synovial microenvironment. The production and contribution of T cell–derived cytokines can be examined on the basis of functional lymphocyte subsets.

## Type 1 T Helper Cell Cytokines

Early investigation into the cytokine profile of RA suggested a bias toward the Th1 phenotype, which produces cytokines such as IL-2 and IFN-γ and expresses the chemokine receptors CXCR3 and CCR5. This process might be driven, in part, by local production of IL-7 by stromal cells and macrophages, which supports the production of Th1 and Th17 cells. Unexpectedly, lower serum IL-7 levels in patients with early-stage inflammatory arthritis are associated with progression to RA.[157] Many T cell clones derived from RA synovial tissue produce a Th1 cytokine pattern. Considerable data have accumulated on the relative abundance and function of the prototypic Th1 cytokine, IFN-γ, which is the most potent inducer of HLA-DR and enhances antigen presentation. IFN-γ also induces adhesion molecules on the surface of endothelial cells and can help recruit inflammatory cell accumulation at sites of injury. One important function of IFN-γ is its capacity to alter the balance of extra-cellular matrix synthesis and degradation by decreasing collagen synthesis and inhibiting MMP production by cytokine-stimulated cultured FLS.[158]

Relatively low concentrations of IFN-γ have been detected in RA joints, which are below the amounts needed to induce HLA-DR expression on monocytes. Immunohistochemical analysis clearly demonstrates IFN-γ in RA synovial T cells, although the percentage is less than in chronically inflamed tonsils. However, the role of IFN-γ is actually quite complex because administration of the cytokine does not exacerbate RA and, if anything, results in improvement in some patients. IFN-γ knockout mice or IFN-γ receptor deficiency can exacerbate collagen-induced arthritis in mice and serve as a reminder that the effects of cytokines can be highly variable depending on the model and timing of expression.

Another major Th1 cytokine, IL-2, is a T cell–derived cytokine that serves as an autocrine or paracrine T cell growth factor. IL-2 is detected in only a small percentage of RA synovial effusions and synovial tissues and, when present, is only found in low concentrations.[159] TNF, GM-CSF, and IL-6 can be expressed by Th1 and Th2 cells and are abundant in synovial fluid and produced by RA

**TABLE 69-5** Partial List of Relative Production of Selected Synovial Cytokines in Rheumatoid Arthritis according to Cellular Source

| Cellular Source | Level of Production in RA Synovium |
|---|---|
| **T Cells** | |
| IL-2 | – |
| IL-3 | – |
| IL-4 | – |

*–, Absent or very low concentrations; +, present.
†Tissue macrophages or type A synoviocytes.
‡Tissue fibroblasts or type B synoviocytes.
APRIL, A proliferation-inducing ligand; BLyS, B lymphocyte stimulator; FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; LIF, leukemia inhibitory factor; LIGHT, lymphotoxin-related inducible ligand that competes for glycoprotein D binding to herpesvirus entry mediator on T cells; MCP-1, monocyte chemoattractant; M-CSF, macrophage colony-stimulating factor; PDGF, platelet-derived growth factor; RA, rheumatoid arthritis; RANKL, receptor activator of NF-κB ligand; TWEAK, TNF-like weak inducer of apoptosis.

synovial tissue. However, the primary sources of these cytokines in the rheumatoid joint are macrophages and fibroblasts.

## Type 2 T Helper Cell Cytokines

Th2 cytokine levels are quite low in rheumatoid joints. Using immunoassays, IL-4 and LTα are generally not detected in RA synovial fluid. In situ hybridization also shows little or no IL-4 mRNA in RA synovial tissue. When sensitive nested reverse-transcriptase polymerase chain reaction techniques are used on synovial biopsies, Th2 cytokines IL-4 and IL-13 are absent in RA, whereas both IFN-γ and IL-12 (a cytokine that regulates T cell maturation toward the Th1 and Th17 phenotypes) are usually present. The Th2 cytokine IL-10, which has potent anti-inflammatory activities, is expressed in RA synovium; however, like many other cytokines, macrophages rather than T cells are the major producers in RA. Some data suggest that synovial fluids in early synovitis have high concentrations of Th2 cytokines such as IL-4 and IL-13 and that this pattern distinguishes patients who progress to RA. As the disease evolves in these patients, the Th2 signature diminishes.[160]

## Type 17 T Helper Cytokines

The discovery of Th17 cells and their critical role in animal models of autoimmunity has generated considerable interest. Th17 cells are also abundant in RA synovial effusions. The pro-inflammatory cytokine produced by Th17 cells, IL-17, is encoded by six genes (IL-17A through F). IL-17A and, to a certain extent, IL-17F mimic and synergize with IL-1 and TNF effects on FLS, including induction of collagenase and cytokine production. IL-17A is present in modest but functionally relevant concentrations in RA synovial effusions.[161] IL-17 receptors IL-17RA and IL-17RC are expressed by synoviocytes and, when engaged, activate the transcription factor NF-κB and initiate an inflammatory cascade. In addition to its effect on mesenchymal cells, IL-17 can participate in bone erosion by enhancing osteoclast activation. Bone resorption in an in vitro model using synovial explants and bone shows that blockade of IL-17, IL-1, and TNF is more effective than blocking the individual factors. IL-21 is also produced by RA T cells, which can serve to further enhance Th17 cell numbers and IL-17 production. Similarly, IL-22 can be produced by Th17 cells and is detected in RA synovial effusions. Like IL-17A, IL-22 activates FLS to produce osteoclast-activating factors such as RANKL.

Immunohistochemistry suggests multiple sources of IL-17. Although IL-17 is present in sublining T cells, some is derived from mast cells. In some studies, IL-17 is present in the synovium of a minority of patients with RA. Immunoreactive IL-17 can be detected near the erosive front of pannus, and thus it likely participates in extra-cellular matrix destruction. Animal models of arthritis demonstrate that IL-17 inhibition is anti-inflammatory and protects animals from bone and cartilage destruction.[162] IL-1, IL-23, and/or TGF-β in the joint can potentially enhance Th17 cell differentiation in humans. BLyS also has the potential to enhance Th17 cell differentiation and promote inflammatory arthritis. All of these cytokines are present in RA synovium, thereby providing an excellent milieu to enhance the generation of these cells.

The role of the IL-17 family is clear and impressive in animal models of arthritis, where blocking IL-17A in particular has dramatic effects on inflammation and matrix destruction. The data in humans are less robust, perhaps because the segregation of human T cells into clear subsets is not as well defined. Clinical studies with anti–IL-17A antibodies and soluble IL-17 receptors in RA are encouraging, but the benefit is modest compared with TNF inhibitors.[163]

## T Helper Cell Cytokine Imbalance

The relative abundance of Th1 and Th17 cells suggests that the synovium resembles a Th1-like delayed-type hypersensitivity reaction and/or a Th17 autoimmune environment. Th2 cytokines and cellular responses that normally suppress Th1 activation are nearly absent, thereby raising the possibility that the lack of T cell activation along the Th2 pathway in RA contributes to disease perpetuation. For example, addition of exogenous IL-10 or IL-4 to cultures of synovial tissue cells or synovial tissue explants suppresses synthesis of pro-inflammatory cytokines and MMPs by cultured RA synovial tissue explants.[164] The inhibitory action of IL-4 might be mediated by decreased c-Jun and c-Fos expression, which is required for efficient production of MMPs and cytokines. In addition, IL-10 and IL-4 increase release of other anti-inflammatory cytokines such as IL-1Ra by synovial cells. Although IL-10 protein is present in RA synovial fluid and the gene is expressed by synovial tissue cells, in vitro studies of cultured synovial cells suggest that not enough IL-10 is produced to suppress IFN-γ production.[165]

The notion that Th1 and Th17 cytokines initiate and perpetuate arthritis, in part as a result of the influence of IL-7, IL-21, and IL-22, whereas Th2 cytokines are suppressive, is supported by studies in animal models. For instance, IL-4 and IL-10 were administered individually or in combination in collagen-induced arthritis.[166] The cytokines had modest or no benefit when used separately, but together the effect was impressive. Clinical improvement correlated with decreased synovial IL-1, TNF, and cartilage destruction. The complexity of cytokine networks in inflammatory arthritis is underscored by studies on the role of IL-12 in collagen-induced arthritis. In early-stage arthritis, IL-12 administration increases the incidence of collagen-induced arthritis, whereas anti–IL-12 is beneficial.[167] However, in late-stage disease, IL-12 administration suppresses arthritis and anti–IL-12 causes an exacerbation. As previously noted, administration of anti–IL-17A antibody to block the prototypical Th17 cytokine provides only a modest benefit. Alternative approaches that inhibit both IL-17A and F, such as soluble receptor constructs, have been tested but do not increase efficacy. The role of Th17 cells is clearer in other inflammatory diseases, most notably psoriasis, where IL-17A blockade demonstrates a robust response.[168] An alternative approach, such as ustekinumab to block IL-12 and IL-23 and subsequent Th17 differentiation, has modest efficacy in RA compared with psoriasis. These data suggest that IL-17 and Th17 cells play a role in RA but are a major contributor in a relatively small subset.

Although enhancing Th2 cytokines is attractive, a clinical trial using IL-10 in RA did not demonstrate significant clinical benefit or improvement in histologic evidence of synovial inflammation.[169] It is possible that combinations of Th2 cytokines will be required to coordinate a maximum effect. Inhibitors of T cell cytokine signaling through JAK3 demonstrate clear efficacy in RA. However, many of these compounds also block JAK1 and could suppress signaling of other cytokines.

## ROLE OF MACROPHAGE AND FIBROBLAST CYTOKINES

**KEY POINTS**

- **Macrophage and fibroblast cytokines are abundant in RA synovium.**
- **Cytokine networks involve pro-inflammatory cytokines such as IL-1, TNF, IL-6, IL-15, IL-18, GM-CSF, and IL-33. These and many other factors help perpetuate synovial inflammation.**
- **Chemokines that recruit inflammatory cells into the joint are commonly produced by macrophages and fibroblasts.**
- **Cytokines with anti-inflammatory activity such as IL-1Ra, IFN-β, and IL-10 are produced in rheumatoid synovium, although in amounts insufficient to suppress pro-inflammatory cytokine function or production.**

Virtually every macrophage and fibroblast pro-inflammatory mediator investigated in the RA synovium is abundant. In this section, some of the major cytokines and effectors produced in the joint are described, with an emphasis on the prevalence of macrophage and fibroblast products as major forces that perpetuate RA. Macrophages, in particular, are the most vigorous producers of cytokines, whereas fibroblasts produce most of the proteases. The role of macrophage and fibroblast cytokines in the pathogenesis of RA was initially suggested by studies involving patient samples, as well as pre-clinical experiments in animal models. Studies that profile blood cytokines and chemokines indicate that panels of these factors increase many years before the onset of clinical disease. Surprisingly, similar increases are found in unaffected first-degree relatives and suggest that combinations of common environmental and genetic factors contribute to this observation.[170]

### Pro-inflammatory Macrophage and Fibroblast Cytokines

#### Interleukin-1 Family

The IL-1 family is a ubiquitous group of polypeptides with a wide range of biologic activity; they include IL-1α, IL-1β, IL-18, IL-33, and IL-1Ra, which is a natural inhibitor of IL-1 (a description of IL-1Ra is provided in a subsequent section). Abundant animal data indicate that IL-1 can serve as a key regulatory factor in inflammatory arthritis. For instance, recombinant IL-1β induces the accumulation of PMNs and mononuclear leukocytes in the joint space and the loss of proteoglycan from articular cartilage when injected directly into rabbit knee joints. Transgenic mice that overexpress IL-1 also develop inflammatory arthritis, whereas mice that lack the natural IL-1 antagonist IL-1Ra have increased susceptibility to collagen-induced arthritis. In most cases, IL-1 blockade in animal models modestly decreases synovial inflammation while markedly diminishing bone and cartilage destruction.

**Interleukin-1.** Synovial macrophages are the most prolific source of IL-1 in the rheumatoid joint, and nearly half of all macrophages in the RA synovium express IL-1β.[171] IL-1 protein is especially found in synovial lining macrophages adjacent to type B synoviocytes and in sublining macrophages near blood vessels. The IL-1 in the lining can subsequently activate type B synoviocytes to proliferate and secrete a variety of mediators. A broad range of stimuli induce IL-1 production by macrophages; for example, immunoglobulin Fc fragments and, to a lesser extent, immune complexes can generate IL-1 production by rheumatoid synovial macrophages. Collagen fragments can induce IL-1 production, and type IX collagen, which has been found only in articular cartilage and localized into intersections of collagen fibrils, is a potent inducer of IL-1 by human monocytes.

Within the rheumatoid joint, IL-1 induces fibroblast proliferation, stimulates the biosynthesis of IL-6, IL-8, and GM-CSF by synovial cells, and enhances collagenase and prostaglandin production. It increases glycosaminoglycan release in human synovial fibroblast cultures, although the effect of IL-1 on the production of intact proteoglycan molecules by intact articular cartilage explants can be the opposite. IL-1 induces a number of adhesion molecules on FLS and endothelial cells, including VCAM-1 and ICAM-1, and enhances bone resorption.

IL-1 has been implicated in RA, but inhibition of this mediator using various IL-1–targeted biologic agents has only a modest clinical benefit. Even combinations of IL-1 and TNF-directed therapy do not provide benefit beyond TNF blockade alone despite biologic effects on acute-phase reactants and rates of infection.[172] In contrast, diseases with a well-defined role for IL-1, such as autoinflammatory diseases, have a much better clinical response. These data suggest that IL-1 plays a modest role in the clinical manifestations of RA.

One explanation for the relatively modest benefit of IL-1 in RA relates to its signaling mechanisms. IL-1 activates NF-κB through the kinase MyD88, which is the same pathway as TLRs. When IL-1 signaling is blocked, it is possible that TLR ligands in the synovium, including exogenous ones such as peptidoglycan or endogenous ones such as HSPs, can provide the stimulus required to overcome IL-1 blockade. This concept was tested in the passive K/BxN model in which mice that lacked the IL-1 receptor had markedly decreased arthritis severity. When small amounts of the TLR4 ligand LPS were administered, robust synovitis ensued. If a similar system occurs in RA, then IL-1 blockade would be unable to control synovitis as long as TLR signaling remains intact.

**Interleukin-18.** In addition to IL-1α and IL-1β, a homologous protein in the IL-1 family known as IL-18 has been implicated in RA. This cytokine was originally defined by its ability to bias the immune response toward the Th1 phenotype, especially in the presence of IL-12. In collagen-induced arthritis, IL-18 inhibition significantly attenuates disease.[173] Subsequent studies showed that IL-18 induces GM-CSF, nitric oxide (NO) production, and TNF

expression by synovial macrophages. IL-18 is expressed by RA synovial tissue, especially by synovial fibroblasts and macrophages, and its production is markedly increased by TNF and IL-1β. A natural inhibitor, the IL-18 binding protein has the potential to be used as a therapeutic agent to block both the pro-inflammatory effects and pro-Th1 effects of IL-18. One potential concern for IL-18 as a target for RA is the fact that the IL-1 convertase inhibitor had only a modest benefit. IL-18, like IL-1β, is processed by this enzyme in order to produce biologically active cytokine. However, an IL-1 convertase inhibitor that blocks both IL-1β and IL-18 release by macrophages also had limited efficacy.

**Interleukin-33 and Other Alarmins.** IL-33 is a novel cytokine that signals through the ST2 surface receptor. Like high-mobility-group box 1 (HMGB1), it is an "alarmin" that provides a danger signal as a result of tissue damage and necrosis with release of intra-cellular contents. Blocking IL-33 decreases inflammation in several animal models of arthritis, including collagen-induced arthritis and antigen-induced arthritis. Mast cells are activated by IL-33 and can subsequently release their content. Thus mast cell–dependent models such as passive K/BxN are less severe in $ST2^{-/-}$ mice.[174] More intriguing, the ability of IL-33 to trigger mast cells could play a role in the release of mast cell products such as TNF and IL-17A in RA synovium. IL-33 can also bias T cells toward the Th2 phenotype, so the fact that it is expressed in RA synovium and synovial effusions raises some questions about its precise function in long-standing disease. HMGB1 is also highly expressed in RA joints and can regulate a number of pro-inflammatory pathways. Blocking HMGB1 decreases damage and immune responses in a variety of autoimmune models. It has also been implicated as a key factor that can convert OA FLS to a more aggressive RA-like phenotype.[175]

## Tumor Necrosis Factor and the Tumor Necrosis Factor Superfamily

The TNF superfamily is an extended group of related genes that play a major role in inflammation, immune responses, cell survival, and apoptosis. At least 19 members of the family have been identified, with TNF identified as the eponymous member. Each cytokine has its own preference for cell surface receptor, although there is some promiscuity of receptor binding and functional overlap. The TNF superfamily members exhibit conserved amino acid sequences, suggesting a single ancestral gene. Many TNF superfamily members include type II membrane protein characteristics and can be released from cell surfaces after proteolytic cleavage. A C-terminal conserved domain called the TNF-homology domain is also shared by several superfamily members. The active forms of the proteins are homotrimers, except for LTα and LTβ, which can form either heterotrimers or homotrimers. Several members have been previously discussed in the relevant sections.

TNF is a pleiotropic cytokine that has been implicated as a key pro-inflammatory cytokine in RA and detected in rheumatoid synovial fluid and serum. It is produced as a membrane-bound protein that is released from the cell surface after proteolytic cleavage by TNF convertase, a membrane MMP. IL-1 and TNF have many similar activities, including the ability to enhance cytokine production, adhesion-molecule expression, proliferation, and MMP production by cultured synoviocytes. In some systems, the effects of these two agents are synergistic. Although they share many functions and signal transduction pathways, IL-1 and TNF use distinct surface receptors and intracellular signaling pathways.

The efficacy of TNF inhibitors in RA demonstrates its critical role in the disease; heterogeneity of the rheumatoid process is also apparent because only about one-third of patients have a dramatic response to TNF inhibitors. Efficacy requires continuous therapy because cessation typically leads to a flare of the disease. Perhaps more interesting, early aggressive therapy with TNF inhibitors can induce long-term remissions in a limited number of patients even after therapy is withdrawn. This exciting notion suggests that interventions in the earliest stages of disease could prevent the establishment of chronic synovitis.

TNF, like IL-1, stimulates collagenase and $PGE_2$ production by human synovial cells, induces bone resorption, inhibits bone formation in vitro, and stimulates resorption of proteoglycan and inhibits its biosynthesis in explants of cartilage. In situ hybridization and immunohistochemical studies show that TNF is primarily produced by synovial macrophages in RA.

Animal models have also supported the general role played by TNF in inflammatory arthritis. For instance, overexpression of TNF in transgenic mice leads to an aggressive and destructive synovitis. In fact, arthritis also spontaneously occurs in transgenic mice that express only a membrane-bound form of TNF on T cells.[176] TNF blockade is an effective anti-inflammatory agent in many animal models of arthritis, although the effects on bone and cartilage destruction are less prominent than with IL-1 inhibitors and are likely mediated through downstream inhibition of IL-1 production.[177] TNF inhibition in RA significantly decreases or prevents joint damage.[178]

TNF blockade is not more effective than traditional agents such as methotrexate or many other biologic agents. Patients with an inadequate response to a TNF inhibitor can still respond to either rituximab or abatacept, which supports the notion that multiple independent pathways can contribute to the pathogenesis of RA and the heterogeneous nature of the disease. Some evidence suggests that some patterns of synovial gene expression are associated with a higher likelihood of a good response to a TNF blocker, but the predictive power is relatively minor.[179] Thus far, various algorithms that include autoantibodies, blood cytokine profiles, and other analytes do not provide enough stratification to be clinically useful. Surprisingly, patients with little or no clinical improvement still have significant delay or arrest of joint damage. This observation supports the concept that inflammation and destruction have distinct pathogenic mechanisms.

## Interleukin-6 Family

IL-6 is a complex cytokine produced by many cell types including T cells, monocytes, and FLS. Originally defined by its B cell–stimulating properties, it induces immunoglobulin synthesis in B cell lines, is involved in the differentiation of cytotoxic T lymphocytes, and is a major factor

in the regulation of acute-phase response proteins like C-reactive protein by the liver. The IL-6 receptor includes a common chain (gp130) that is shared with other cytokines and an IL-6–specific chain (IL-6R). IL-6R can be shed from cell surfaces, it can bind to IL-6, and it can be delivered to cells that lack IL-6 receptors by combining with gp130. IL-6 signaling proceeds through the JAKs, especially JAK1, and phosphorylation of STAT3.

A striking correlation between serum IL-6 activity and serum levels of acute-phase reactants such as C-reactive protein, $\alpha_1$–anti-trypsin, fibrinogen, and haptoglobin occurs in patients with RA. Very high levels of IL-6 are present in RA synovial fluid, and synovial cells in culture from diverse inflammatory arthropathies produce IL-6. In situ hybridization of synovial tissue also shows IL-6 mRNA in the intimal lining, and immunohistochemistry studies show IL-6 protein in the lining and sublining regions. Although many synovial macrophages express the IL-6 gene, the majority of IL-6 appears to be produced by type B synoviocytes.

The pivotal role of IL-6 in RA has been demonstrated by clinical trials using monoclonal antibodies that bind to IL-6R or to IL-6 itself. The clinical responses are similar to TNF inhibitors, including protective effects on bone and cartilage damage.[180] IL-6R antibody is also effective in patients who have not responded to TNF blockade. This observation is surprising considering that TNF is considered upstream of IL-6 in the cytokine cascade and that TNF inhibition markedly decreases IL-6 levels in RA. Neutropenia, increased liver enzymes, and altered blood lipids have been observed with IL-6 inhibition, although the relative importance of these observations is still uncertain. JAK inhibitors have also demonstrated efficacy in RA, which might be due in part to the effect on IL-6 signaling.

Cytokines with structural similarity to IL-6 and that share receptor subunits have also been implicated in RA. Several of these cytokines—IL-11, leukemia inhibitory factor (LIF), and oncostatin M—are expressed by rheumatoid synovium and can be detected in synovial effusions. The biologic effects of these factors are complex and can be either protective (e.g., by increasing expression of protease inhibitors such as tissue inhibitors of metalloproteinase [TIMP]) or pro-inflammatory (e.g., by increasing expression of chemokines or MMPs), depending on the culture conditions or the specific model evaluated. This dichotomy among the family members is demonstrated by the fact that IL-11 administration ameliorates collagen-induced arthritis, whereas antibodies to oncostatin M are protective.

### Interleukin-12 Family

The IL-12 family includes a group of cytokines that play a key role in the differentiation of T cells and inflammation. IL-12 is a heterodimeric cytokine with two subunits (e.g., p35 and p40) encoded on separate genes and produced by antigen-presenting cells. IL-23 and IL-27 have similar heterodimeric structures to IL-12, with p29/p40 and p28/EB13 components, respectively. In the context of antigen presentation, IL-12, IL-23, and IL-27 can bias T cell responses toward the Th1 phenotype. IL-23 can also play a pivotal role in the production of Th17 cells, along with IL-1 and TGF-β. The IL-12 family of cytokines are generally produced by macrophages in the rheumatoid joint but are also produced by other antigen-presenting cells such as DCs. Although clinical data defining the role of these cytokines are still lacking, anecdotal case reports indicate that patients with RA who have undergone treatment of malignancy with recombinant IL-12 experienced a flare of the disease. In contrast to psoriasis and psoriatic arthritis, where the IL-23-blocking biologic ustekinumab shows efficacy, this agent has limited efficacy in RA.[180a] This experience is similar to IL-17-blocking strategies in RA and psoriasis. Animal models, including adjuvant arthritis in rats and collagen-induced arthritis in mice, show that disease is partially ameliorated by neutralization of IL-12, IL-23, or IL-27, depending on the timing of treatment. In some situations, however, IL-27 has anti-inflammatory effects.

### Interleukin-15

IL-15 is an IL-2–like cytokine that regulates numerous immunologic functions relevant to RA, including T cell chemotaxis and proliferation, production of immunoglobulins by B cells, and the generation of NK cells. Although IL-15 can serve as an IL-2–independent mechanism for activating T cells, its role in RA may be related to its key role in TNF regulation. Macrophages are the primary source of IL-15 in RA, and the cytokine is able to induce a cell-contact mechanism of macrophage TNF production that requires T cells. Although T lymphocytes are required for this process, macrophages actually produce the TNF. This network provides a potential mechanism whereby local IL-15 production in the synovium can lead to autocrine production of TNF in a T cell–dependent but antigen-independent fashion. IL-15 has been demonstrated in RA synovial macrophage cells. Soluble IL-15 receptors can function as an IL-15 inhibitor, and when used in vivo, they can decrease joint inflammation in collagen-induced arthritis. Clinical trials in RA using an anti–IL-15 antibody had a signal for efficacy, although it was not sufficient to continue developing this particular biologic agent.[181]

### Interleukin-32

IL-32 activates NF-κB and induces the production of several pro-inflammatory cytokines and chemokines, including TNF, IL-1, IL-6, and IL-8. It has been implicated in Crohn's disease by virtue of its ability to markedly enhance caspase 1 activation and IL-1 production in cells that have been exposed to muramyl dipeptides. IL-32 is expressed by RA synovial tissue, especially in synovial-lining macrophage-like cells.[182] The level of IL-32 expression correlates with the presence of other cytokines implicated in RA, including TNF, IL-1, and IL-18. Injection of IL-32 into the joints of naïve mice causes a robust transient synovitis. The synovial response could be partially abrogated by anti-TNF antibodies, suggesting that IL-32 induces this cytokine in vivo. These data suggest that IL-32 might be upstream from several pro-inflammatory mediators in RA and could represent a therapeutic target.

### Colony-Stimulating Factors

GM-CSF supports the differentiation of bone marrow precursor cells to mature granulocytes and macrophages. As

with other major CSFs, GM-CSF also participates in normal immune responses. It is a potent macrophage activator, including the induction of HLA-DR expression, IL-1 secretion, intra-cellular parasite killing, and priming for enhanced release of TNF and $PGE_2$. Neutrophil function is also regulated by GM-CSF, which enhances antibody-dependent cytotoxicity, phagocytosis, chemotaxis, and the production of oxygen radicals.

RA synovial fluid and synovium contain GM-CSF.[183] The major source is synovial macrophages, although IL-1– or TNF-stimulated FLS also express the *CSF2* gene (which encodes GM-CSF). Its ability to induce HLA-DR gene expression on macrophages might be of particular importance in RA. GM-CSF, not IFN-γ, is the major DR-inducing cytokine in RA synovial effusions. Collagen-induced arthritis in mice is less severe in animals that lack a functional *CSF2* gene or are treated with anti–GM-CSF antibody, which supports the hypothesis that *CSF2* is an important pro-inflammatory mediator. Clinical trials demonstrate potential clinical benefit with an anti–GM-CSF antibody in RA, although long-term efficacy and safety still must be evaluated.[184] Some concern exists that pulmonary alveolar proteinosis might be an adverse event because this syndrome develops in *GM-CSF*–deficient mice and in autoimmune diseases marked by spontaneous production of anti–GM-CSF antibodies.

Macrophage CSF (M-CSF) is also expressed by RA synovium and is present in synovial effusions. Its primary pathogenic role in RA probably relates to its osteoclast-differentiating capacity. This factor cooperates with RANKL to facilitate bone erosions. The M-CSF receptor also binds to a novel cytokine that is produced by FLS, namely IL-34. The cytokine is expressed in RA synovium and represents an alternative therapeutic target for M-CSF receptor-driven events in synovitis.[185]

### Interferons

Type I IFNs, especially IFN-β, are expressed by RA synovium. The IFNs possess a range of biologic activities and can be immunostimulatory or inhibitory depending on the context. In murine models of arthritis, exogenous IFN-β has prominent anti-inflammatory activity. However, a similar benefit has not been observed in RA. One possible explanation relates to the mechanism of action in arthritis: In murine models, IFN-β appears to act by increasing IL-1Ra production.[186] Although IL-1 is a key therapeutic target in pre-clinical models, it is less important in RA. Thus IFN-β does actually increase synovial IL-1Ra production in patients with RA, but blocking IL-1 is not sufficient for robust clinical effects. Another IFN, IL-29, has recently been identified in RA synovium. In vitro studies show that IL-29 can increase IL-6, IL-8, and MMP production by cultured FLS.[187]

### Chemokines

Chemokines are a family of related chemoattractant peptides that, with the assistance of adhesion molecules, summon cells into inflammatory sites. They are generally divided into families including CC, CXC, and CX3C based on the position of characteristic cysteine residues.

Many chemokines have been identified in the rheumatoid joint. IL-8, a CXC chemokine that was originally characterized as a potent chemoattractant for neutrophils, along with immune complexes and other chemotactic peptides such as C5a, contribute to the large influx of PMNs into the joint. Immunohistochemical analysis of synovial tissue demonstrates IL-8 protein in sublining perivascular macrophages, as well as in scattered lining cells.[188] Cultured synovial tissue macrophages constitutively produce IL-8, and FLS express the same gene if they are stimulated with IL-1 or TNF. IL-8 accounts for about 40% of the neutrophil chemoattractant activity in synovial fluid. In addition, IL-8 activates neutrophils through G protein–coupled receptors and is a potent angiogenesis factor.

Many other chemoattractant proteins are implicated in RA. Macrophage-inhibitory protein-1α, macrophage-inhibitory protein-1β, MCP-1, and "regulated on activation, normally T cell expressed and secreted" (RANTES)—members of the CC subfamily—are produced by RA synovium, as are many other CC chemokines.

CXCL16 and epithelial neutrophil-activating peptide-78 (ENA-78) are CXC chemokines and are also abundant, along with many others in that family.[189] CXCL16, which binds to CXCR6 on T cells, can contribute to the recruitment of lymphocytes into the synovium. ENA-78 accounts for about 40% of the chemotactic activity for neutrophils in RA synovial fluid. Concentrations of these chemokines are higher in RA synovial effusions compared with non-inflammatory arthritides such as OA. Although the chemokines also can be detected in the blood, the levels are considerably lower than in the joint, thereby providing a gradient that signals cells to migrate into the synovium.

Lymphocyte-specific chemotactic factors contribute to the germinal center architecture of RA. The CXC factor B cell–activating chemokine-1 (BCA-1; CXCL13) binds to specific CXCR5 receptors on B cells. CXCL13 is expressed in the RA synovial tissues, especially by follicular DCs in germinal centers, and likely accounts for B cell migration to these regions.[190] CCL21 and several other factors participate in the anatomic organization of germinal centers, marginal zones, and other regions of lymphoid follicles. Another chemokine, SDF-1, is expressed by synoviocytes and endothelial cells and can play a major role as a chemoattractant for T cells in synovium via its receptor, CXCR4. Unlike other chemokine receptors that can bind multiple members of the family, CXCR4 is highly specific for SDF-1 and is expressed by memory $CD4^+$ lymphocytes.

Chemokines have attracted considerable attention as therapeutic targets to prevent recruitment of immune cells into the synovium. Numerous pre-clinical models support the use of chemokine blockers. For instance, antibodies to fractalkine (CXC3L1) suppress murine collagen-induced arthritis, even though anti–type II collagen antibody production was not affected.[191] Anti-CXCL16 antibody also decreases clinical arthritis in the same model. One problem is that the system is highly redundant and several different chemotactic proteins can bind to the same receptor. No clinical improvement in RA was observed in a study using anti–MCP-1 antibody, perhaps because the antibody also altered the kinetics of MCP-1 metabolism. Anti–IL-8 antibodies have met with limited success in psoriasis. More

promising results were observed with antibody to IP-10 (CXCL10), which demonstrated some efficacy in a phase II study in RA.[192]

Alternatively, chemokines bind to G protein–coupled receptors and can be targeted to block multiple factors. For instance, CCR1 antagonists, which block RANTES and MIP-1α, have been evaluated in clinical trials.[193] Although one compound significantly decreased synovial infiltration by CCR1-expressing cells, no significant improvement was observed. Chemokine receptor blockade has other levels of complexity such as CCR2-deficient mice, which develop more severe arthritis in some models. Several CCR2 antagonists, which block MCP-1, have not demonstrated significant efficacy in RA. These data suggest that the chemokine system, including the receptors, is both redundant, complex, and, in some cases, perhaps protective in arthritis.

Chemokines and other chemotactic factors (such as C5a and $LTB_4$) can signal through a variety of mechanisms, although many pathways converge on PI3K. Of the several PI3K isoforms, PI3Kγ is relatively specific for chemokine signal transduction, which provides an opportunity to block multiple chemokine receptors simultaneously. Proof of concept for this approach was provided by studies in PI3Kγ knockout mice, which have less synovial inflammation in passive and active collagen-induced arthritis than in wild-type mice.[194] Therefore, targeting shared intra-cellular pathways could potentially overcome some of the limitations presented by the complex chemoattractant system.

### Platelet-Derived Growth Factor and Fibroblast Growth Factor

PDGF is a potent growth factor that is both a chemoattractant and a mitogen for fibroblasts and induces collagenase expression. It is the most potent stimulator of long-term growth of synovial cells in culture. PDGF is expressed in vascular endothelial cells, platelets, and other synovial sublining cells in rheumatoid synovium, compared with healthy tissue. Multiple isoforms of this molecule have been identified (PDGF A through D), all of which have been detected in RA synovial membranes. PDGF D has been identified as an especially potent stimulator of MMP-1 expression in cultured synoviocytes. PDGF is a potent activator of the PI3K pathway, which leads to Akt phosphorylation and supports synoviocyte survival through activation of the α and δ isoforms.

FGFs are a family of peptide growth factors with pleiotropic activities. In patients with rheumatoid disease, it is likely that heparin-binding growth factor, the precursor of acidic fibroblast growth factor, is a major mitogen for many cell types and stimulates angiogenesis. Interactions between FGF and proteoglycans is required for biologic activity. It is a potent angiogenic factor, inducing capillary endothelial cells to invade a three-dimensional collagen matrix and form capillaries. Synoviocytes can also be induced to increase expression of RANKL by FGF, thereby enhancing osteoclast activation and bone resorption. FGF is present in RA synovial fluid, and the genes are expressed by synovial cells. Synovial fibroblasts express FGF receptors and proliferate after exposure to the growth factor.

## Immunosuppressive Cytokines and Cytokine Antagonists

The pro-inflammatory cytokine network in RA is offset by a variety of suppressive and anti-inflammatory factors that attempt to re-establish homeostasis. Low production of these suppressive cytokines could contribute to the perpetuation of the synovitis. Many cytokine antagonists or natural immunosuppressives represent potential therapeutic targets for the treatment of inflammatory diseases.

### Interleukin-1 Receptor Antagonist

IL-1Ra is a naturally occurring IL-1 inhibitor that binds directly to types I and II IL-1 receptors and competes with IL-1 for the ligand-binding site. Interaction of IL-1Ra with the IL-1 receptors does not result in signal transduction, and, in contrast to IL-1α or -β, the receptor-ligand complex is not internalized after it binds to the IL-1 receptor. Even though IL-1Ra has high affinity for the IL-1 receptor, it is a relatively weak inhibitor because IL-1 can activate cells even if only a small percentage of IL-1 receptors is occupied. As a result, a substantial excess of the inhibitor is required to saturate the receptor and thereby block IL-1–mediated stimulation (usually 10- to 100-fold excess of IL-1Ra).

IL-1Ra is present in rheumatoid synovial effusions; much of it is produced by neutrophils and macrophages.[195] In RA synovium, IL-1Ra protein is found in perivascular mononuclear cells and in the synovial intimal lining. The IL-1Ra protein and mRNA can be detected in synovial macrophages and, to a lesser extent, in type B synoviocytes (Figure 69-12). The presence of IL-1Ra in synovium is not specific to RA because OA synovial tissue also contains IL-1Ra, albeit in lesser amounts. Normal synovium contains little, if any, IL-1Ra protein. Synovial cell culture experiments show that the amount of IL-1Ra is insufficient to antagonize synovial IL-1.

### Interleukin-10

IL-10 is an immunosuppressive cytokine that was originally characterized as an inhibitor of T cell cytokine production. Its immunosuppressive actions might be important in pregnancy to suppress an immune response directed against paternal MHC antigens, and it might regulate susceptibility to some parasitic infections. As noted previously, IL-10 protein is present in RA synovial fluid, and the gene is expressed by synovial tissue macrophages. Serial synovial biopsies in patients with RA who were treated with recombinant IL-10 did not show any significant histologic improvement, and clinical responses were not impressive in a limited study.

### Transforming Growth Factor-β

TGF-β is a key member of the TGF superfamily, which includes the bone morphogenic proteins that signal through intra-cellular signaling molecules known as *Smads*. TGF-β is widely distributed in different tissues and is produced by many cells, including T cells, monocytes, and platelets. It suppresses the production of collagenase and induces the expression of TIMP. TGF-β accelerates the healing of

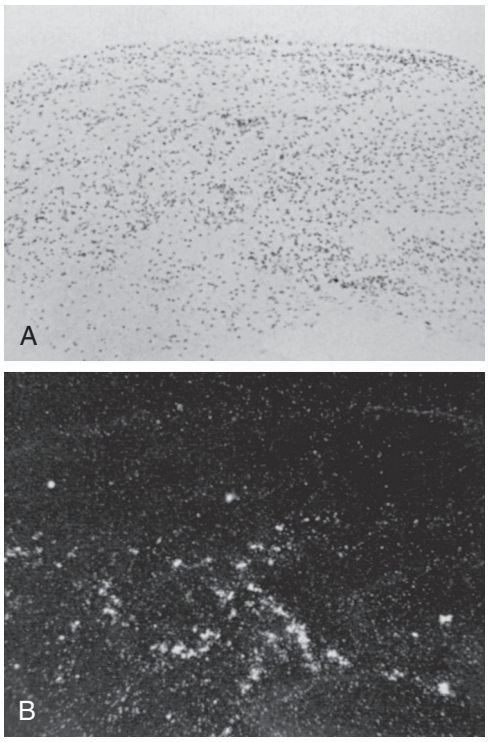

**Figure 69-12** Localization of IL-1 receptor antagonist (IL-1Ra) messenger RNA in rheumatoid arthritis synovial tissue by in situ hybridization. The specific RNA transcript was detected in perivascular cells, especially macrophages. **A,** Bright field view. **B,** The same area using a dark field filter. Silver grains in the dark field view show the location of IL-1Ra$^+$ cells.

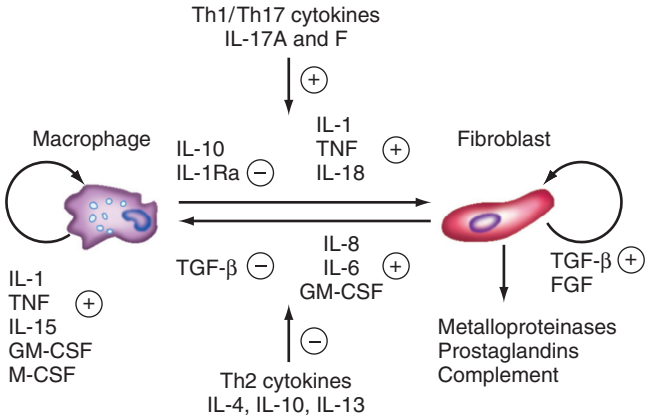

**Figure 69-13** Cytokine networks in rheumatoid arthritis (RA). Paracrine and autocrine pathways can lead to activation of fibroblast-like and macrophage-like synoviocytes in the synovial intimal lining. Both positive (+) and negative (–) feedback loops are present, although in RA the former predominate. Type 1 T helper (Th) or Th17 cytokines can potentially enhance the network, whereas Th2 cytokines are suppressive. FGF, Fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; M-CSF, macrophage colony stimulating factor; TGF, transforming growth factor.

incisional wounds and induces both fibrosis and angiogenesis in experimental models with animals. Substantial amounts of TGF-β are present in synovial fluid, although it is mainly present in an inactive, latent form, and the mRNA can be detected in RA synovial tissue.[196] Although typically considered an immunosuppressive cytokine with wound-healing properties, the role of TGF-β in RA is complex.

In RA, TGF-β is one of the factors responsible for blunted responses of synovial fluid T cells. TGF-β also downregulates IL-1 receptor expression on some cell types, including chondrocytes. When it is injected directly into the knees of animals, fibrosis and synovial lining hyperplasia develop. In streptococcal cell wall arthritis, parenteral administration or systemic gene therapy with the TGF-β gene ameliorates the disease. However, intra-articular administration of anti–TGF-β antibody decreases arthritis in the injected joint but not in the contralateral joint in the same model. Although mainly considered anti-inflammatory, TGF-β also plays a key role in the development of autoimmunity through the differentiation of T cells into the Th17 phenotype.

### Soluble Cytokine Receptors and Binding Proteins

Soluble cytokine receptors and binding proteins can absorb free cytokines and prevent them from engaging functional receptors on cells. Although these inhibitors can block cytokine action, they also could act as carrier proteins that protect cytokines from proteolytic degradation or deliver them directly to cells such as the IL-6 receptor.

TNF receptors are normally expressed as membrane-bound proteins and can be released from the cell surface after proteolytic cleavage. Soluble p55 and p75 TNF receptors have been detected in RA synovial fluid, sometimes in high concentrations. Based on studies with TNF inhibitors and soluble TNF receptor-Fc fusion proteins like etanercept, it is clear that the levels of soluble TNF receptors are not high enough to block TNF biologic activity.

Many other soluble receptors and binding proteins are produced in RA, albeit in concentrations too low to effectively suppress the pro-inflammatory cytokine milieu of the joint. For instance, the IL-1 type II receptor is present in RA synovial fluid, along with lesser amounts of the type I receptor. These soluble receptors can bind to IL-1 or IL-1Ra in synovial effusions. Soluble receptors to IL-15 and IL-17 that neutralize their respective ligands have been characterized, and an IL-18 binding protein also can inhibit cytokine activity.

## Perpetuation of Synovitis by Cytokine Networks

Mapping the cytokine profile in RA led to targeted biologic therapy to inhibit cytokines and supports the concept that cytokine networks play a key role. The network pathway is not autonomous and, except for certain patients with very early disease, discontinuation of anti-cytokine therapy allows the disease to flare. Nevertheless, paracrine and autocrine cytokine networks in the synovial intimal lining contribute largely to inflammatory arthritis in RA (Figure 69-13).

Several cytokines that have been identified in the synovium or synovial fluid can participate in this system and might explain lining cell hyperplasia, HLA-DR and adhesion-molecule induction, and synovial angiogenesis.

The list of potential candidates in this highly redundant system is extensive. Several of these candidates, including IL-1, TNF, and IL-6, now have well-defined roles. The first two, along with numerous other factors (e.g., IL-15, IL-18, and IL-32), are produced by synovial macrophages and stimulate synovial fibroblast proliferation and secretion of IL-6, GM-CSF, and chemokines, as well as effector molecules such as MMPs and prostaglandins. GM-CSF, which is produced by both synovial macrophages and IL-1β– or TNF-stimulated synovial fibroblasts, can, in turn, induce IL-1 secretion to form a positive feedback loop. GM-CSF, especially in combination with TNF, also increases HLA-DR expression on macrophages. Macrophage and fibroblast cytokines also could indirectly contribute to the evidence for local T cell and B cell activation, including RF and ACPA production. Newly implicated members of the macrophage-fibroblast cytokine network such as IL-33 and HMGB1 can activate other cell lineages such as mast cells that have attracted increased attention in recent years.

The cytokines can then recruit other immune and inflammatory cells into the synovium through the production of chemokines that select specific cell lineages for admission and retention in the synovium. Many of these chemokines, including the CXC and CC families, are produced by macrophages and fibroblasts and attract neutrophils, macrophages, and specific subpopulations of T and B cells. The sublining chemokine profile including CXCL13 and CCL20 helps organize these newly infiltrated cells into organized lymphoid structures in some patients. Other factors such as IL-12 and IL-23 differentiate $CD4^+$ T cells into the Th1 phenotype to produce relatively small amounts of IFN-γ and other relevant cytokines. IL-1 and TGF-β produced mainly by the lining can, along with IL-23, support the production of Th17 cells that release the potent IL-17 family members into the local milieu. All of this occurs in the presence of inhibitor factors, soluble receptors, and binding proteins that are overwhelmed by the inflammatory drive. Other cytokines, such as RANKL and M-CSF, activate osteoclasts that remodel bone.

Even though cytokines might not cause RA per se, they clearly orchestrate and perpetuate rheumatoid synovitis. The pivotal cytokine or cytokines that must be blocked could be different for individual patients, and even this could vary with the stage of disease. Ultimately, understanding the genetic predisposition, environmental triggers, and specific patterns of cytokine production could help determine the correct combination of cytokine inhibitors that will be effective.

## SIGNAL TRANSDUCTION AND TRANSCRIPTION FACTORS

**KEY POINTS**

- **Complex intra-cellular signaling mechanisms regulate cytokine production and actions in RA synovium.**
- **NF-κB, MAP kinases, activator protein-1 (AP-1), JAKs, Syk, PI3Ks, and several other pathways are potential therapeutic targets in RA.**
- **Signal transduction inhibitors have demonstrated clinical efficacy in RA.**

Intra-cellular signal transduction systems transmit information from the environment to the interior of a cell, which can then respond appropriately to stress. The remarkable diversity of signaling pathways and transcription factors provides a selective mechanism for orchestrating activation and repression for appropriate genes. Many of the inflammatory responses observed in RA synovium, including the activation of cytokine, proteases, and adhesion-molecule genes, can be traced to specific transcription factors and signal transduction pathways.

### Nuclear Factor-κB

NF-κB is a ubiquitous transcription factor that plays a key role in the expression of many genes central to RA, including IL-1, TNF, IL-6, and IL-8. It is abundant in rheumatoid synovium, and immunohistochemical analysis demonstrates p50 and p65 NF-κB proteins in the nuclei of cells in the synovial intimal lining.[197] Although the proteins also can be detected in OA synovium, NF-κB activation is much greater in RA because of phosphorylation and degradation of IκB in RA intimal lining cells. Nuclear translocation of NF-κB in cultured FLS occurs rapidly after stimulation with many pro-inflammatory cytokines (e.g., IL-1, TNF, and IL-17) or TLR ligands (e.g., peptidoglycan and LPS). NF-κB is also a major survival factor for cells and is responsible for resistance to apoptosis in some cell lineages after activation. This characteristic is especially important in intestinal inflammation, where IKKβ deficiency actually increases mucosal damage because the lack of NF-κB can increase cell death in epithelium.[197a]

The relevance of NF-κB to inflammatory arthritis has been tested in several animal models. Synovial NF-κB is rapidly activated, often long before clinical arthritis is evident. Adjuvant arthritis in rats is ameliorated using intra-articular gene therapy with the dominant negative IKKβ construct that blocks the IKK pathway, and streptococcal cell-wall arthritis is blocked with decoy oligonucleotides or a dominant negative IκB adenovirus.[198] NF-κB inhibition is associated with decreased synovial cellular infiltration, as well as increased apoptosis. Small molecule IKKβ inhibitors also suppress arthritis and joint destruction in murine collagen-induced arthritis.

### Activator Protein-1

Like NF-κB, AP-1 regulates many genes implicated in RA, especially TNF and the MMPs. AP-1 activity can be induced by extra-cellular signals including cytokines, growth factors, tumor promoters, and the Ras oncoprotein. AP-1 includes members of the Jun and Fos families of transcription factors that form Jun homodimers, Jun-Jun heterodimers, or Jun-Fos heterodimers. AP-1–driven gene expression is greatly enhanced when one of its components, including c-Jun, is phosphorylated by the c-Jun N-terminal kinase (JNK).

AP-1 proteins and nuclear binding are elevated in RA synovium, especially in the nuclei of cells in the intimal lining layer.[199] c-Jun and c-Fos proteins are also expressed in the sublining inflammatory infiltrate, albeit to a lesser degree. Localization of AP-1 to the intimal lining correlates with the site where most protease and cytokine genes are overexpressed in RA. AP-1 proteins are usually not detected

in normal synovium, although modest amounts have also been detected in OA.

Cytokines such as IL-1 and TNF and TLR ligands contribute to the activation of AP-1 in RA synovium. These factors are potent inducers of AP-1 nuclear binding in cultured FLS. IL-1 is particularly effective and can dramatically increase AP-1 binding at very low concentrations. The specific Jun family members that constitute AP-1 in synoviocytes have a clear effect on function. For instance, c-Jun increases the production of pro-inflammatory mediators, whereas JunD suppresses cytokine and MMP production.[200] AP-1 decoy oligonucleotides suppress collagen-induced arthritis and inhibit cytokine production by synovial tissue.

## Mitogen-Activated Protein Kinases

MAP kinases are signal transduction enzymes activated in response to cellular stress and are composed of parallel protein-kinase cascades that regulate cytokine and MMP gene expression. There are three main families of MAP kinases known as JNK, p38, and extra-cellular signal-regulated kinase (ERK). MAP kinases phosphorylate selected intra-cellular proteins, including transcription factors, which subsequently regulate the expression of various genes by transcriptional and post-transcriptional mechanisms. MAP kinases are activated by phosphorylation at conserved threonine and tyrosine residues by a cascade of dual-specificity kinases that are, in turn, activated by MAP kinase kinases. The relative hierarchy of the individual MAP kinases depends on the cell type and inflammatory stimulus.

The MAP kinases are widely expressed in synovial tissue and are activated in rheumatoid synovium. Phosphorylated ERK, p38, and JNK can be detected by immunohistochemistry or Western blot analysis. All three kinases and their upstream regulators are constitutively expressed by cultured FLS and can be activated within minutes after exposure to cytokines. They regulate production of pro-inflammatory cytokines and MMPs.

p38 inhibitors are effective anti-inflammatory agents in murine collagen-induced arthritis and rat adjuvant arthritis, possibly by decreasing the production of pro-inflammatory cytokines. In addition, p38 inhibitors block TNF and IL-6 production by cultured macrophages and synoviocytes, as well as cultured synovial tissue cells. Spinal p38 also plays a major role in pain processing, and inhibitors have potential for both analgesic and anti-inflammatory action. Recent studies suggest that p38 in the central nervous system can regulate peripheral inflammation because intrathecal administration of a p38 inhibitor suppresses inflammation and joint destruction in rat adjuvant arthritis.[200a]

Given the putative role of p38 in RA, it is surprising that clinical efficacy of the selective p38 inhibitors is modest, at best.[201] Clinical response rates are rarely greater than 40%, compared with the 60% range for TNF blockers. Perhaps more interesting, an initial decrease in acute-phase reactants is only transient despite adequate drug levels. Recent data in mice that lack p38α in macrophages shed some light on the mechanisms. In the passive K/BxN serum transfer model, paradoxically, disease increases in these mice[202] (Figure 69-14). The p38-deficient macrophages have lower production of the anti-inflammatory cytokine IL-10. In addition, expression of phosphatases that deactivate other MAP kinases is suppressed, resulting in markedly higher levels of phosphorylated JNK and ERK. Thus a compensatory increase in pro-inflammatory pathways abrogates the beneficial effect of p38 inhibition.

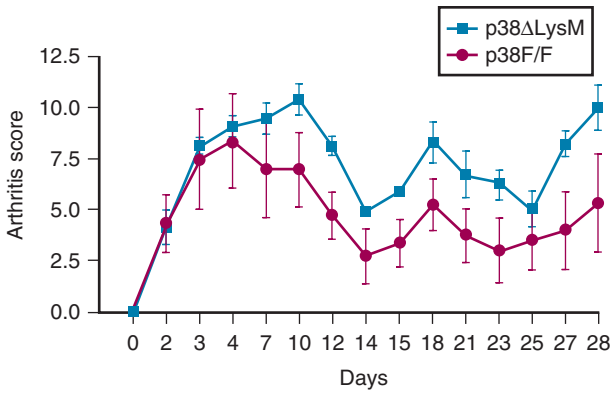

**Figure 69-14** Increased arthritis in mice lacking p38 in macrophages. Mice with p38-deficient macrophages (p38ΔLysM) and control mice (p38F/F) were injected twice with arthritogenic serum from K/BxN mice to create a chronic arthritis model. Note that the mice lacking p38 in macrophages have increased disease severity, most likely because of decreased levels of IL-10 production and increased activation of other mitogen-activated protein kinases. *(From Guma M, Hammaker D, Topolewski K, et al: Anti-inflammatory functions of p38 in mouse models of rheumatoid arthritis: advantages of targeting upstream kinases MKK-3 or MKK-6.* Arthritis Rheum *64:2887-2895, 2012.)*

Instead of blocking p38 directly, an upstream kinase might be targeted. MKK3 and MKK6, both of which regulate p38, are expressed and activated in the rheumatoid synovium. MKK3 knockout mice and MKK6 knockout mice have markedly decreased joint inflammation in the passive K/BxN model and collagen-induced arthritis.[203] Notably, the MKK3 or MKK6 deficiency in macrophages avoids the effect of p38 blockade on ERK, JNK, and IL-10. The upstream kinases represent alternatives to targeting the MAP kinases themselves.

The other two MAP kinases are also potential therapeutic targets. The ERK pathway, which regulates cell growth and some inflammatory mediators, can be blocked by inhibiting its upstream kinases MEK1 and MEK2. One clinical trial with a small molecule inhibitor found minimal benefit, although the placebo response rate was high.

Two of the three JNK isoforms (JNK1 and JNK2) regulate a variety of genes in inflammation, including TNF and metalloproteinases. Using a JNK inhibitor, marked protection of bone destruction was observed in the adjuvant arthritis model, along with decreased synovial AP-1 activation and collagenase gene expression.[204] No benefit was observed in the $JNK1^{-/-}$ mice, and only modest cartilage protection was seen in the $JNK2^{-/-}$ animals.

Like p38, the upstream kinases in the JNK pathway are activated in RA synovium and FLS. MKK4 and MKK7 are the main kinases that modulate JNK function. Only MKK7 is required for cytokine-stimulated JNK activation and MMP expression in cultured synoviocytes.[205] Using antisense oligonucleotides to decrease MKK7 expression, mice have decreased arthritis severity and JNK activation in the passive K/BxN model.[206]

## Janus Kinases and the Signal Transducers and Activators of Transcription

The JAK proteins are key proteins that transduce signals from a wide variety of cytokine and growth factor receptors. Four JAKs have been identified (JAK1, JAK2, JAK3, and TYK1), and they can form heterodimers and homodimers. The specific JAK proteins responsible for individual cytokine responses are not fully elucidated, but some general guidelines are available. JAK3 provides the signaling for many T cell–derived cytokines, and mutations in this gene are responsible for severe immunodeficiency. JAK1/JAK2 is responsible for the IL-6 family and interferons. JAK2/JAK2 signals for growth factors such as erythropoietin and cytokines related to Th17 cell differentiation like IL-23. The distribution and expression levels for JAKs in RA are not well defined. However, all four genes are expressed in cultured FLS and immunohistochemistry studies localize JAK3, especially in sublining DCs.[207]

The JAK proteins have become a focus of interest because of the efficacy demonstrated by several JAK inhibitors in RA, including tofacitinib.[208] The benefit observed is similar to biologic agents, although the importance of toxicity related to host defense, liver enzymes, neutropenia, renal function, and potentially oncogenesis requires further study. The best isoform specificity also needs to be defined to maximize safety and efficacy. Because IL-6 signals through kinases such as JAK1, one could anticipate that this particular signaling molecule would be especially important for RA. On the other hand, a more T cell–directed approach for indications such as transplantation might focus more on JAK3 and could potentially have longer term benefits in complex diseases of innate and adaptive immunity.

The JAK proteins phosphorylate the STATs. The STATs can then translocate to the nuclei, where they can alter gene transcription. STATs have been implicated in the expression of many pro-inflammatory genes. Although there is some variation depending the stimulus, IFNs signal through STAT1, IL-6 signals through STAT3, and IL-12 signals through STAT4.

Multiple STATs are expressed in rheumatoid synovium. STAT1 activation correlates with disease activity in RA (Figure 69-15), and a STAT1 decoy oligonucleotide suppresses antigen-induced arthritis in mice.[209] In addition, studies of rheumatoid tissue have an expression signature suggesting STAT1-regulated gene expression, including IFN-regulated genes. Another study suggested that patients with RA could be divided into a group with a STAT1 signature and the other with a signature reminiscent of tissue repair and remodeling.[210]

A synovial biopsy study in patients receiving the JAK inhibitor tofacitinib showed a close correlation between clinical responses and phospho-STAT1 and phospho-STAT3.[210a] These data suggest that JAK1 inhibition is especially important for clinical efficacy, most likely by blocking IL-6 and type I IFNs.

## Interferon Regulation: IKK-Related Kinases and Interferon Regulatory Factors

IFN signatures have been noted in several autoimmune diseases, including RA. Type I IFNs are expressed in RA synovium, especially by synoviocytes in the intimal lining. Regulation of IFN production and the IFN response genes such as *CCL5*, *CXCL10*, and *CCL2* involves a pathway that runs parallel to the canonical NF-κB pathway and includes two IKK-related kinases, known as IKKε and TANK binding kinase 1 (TBK1). Triggered when TLR3 is ligated by viral dsRNA, IKKε, and TBK1 phosphorylate the transcription factor IFN regulatory factor 3 (IRF3) and induce production of an array of genes that orchestrate this response, including RANTES and IFN-β. IKKε and its substrate IRF3 are expressed and highly activated in RA synovium. Using a combination of $IKK\varepsilon^{-/-}$ mice and genetic constructs that block endogenous IKKε and TBK1 activity, the IKK-related kinases were shown to be a key regulator of IFN-β, RANTES, and MMP expression in cultured FLS.[211] In contrast to DCs, where IRF7 is the primary IRF that regulates IFN responses, IRF3 is the pivotal factor that is responsible for the IFN signature.[212]

Overexpression of some IRF3-driven genes, most notably IFN-β, could have a beneficial impact in inflammatory

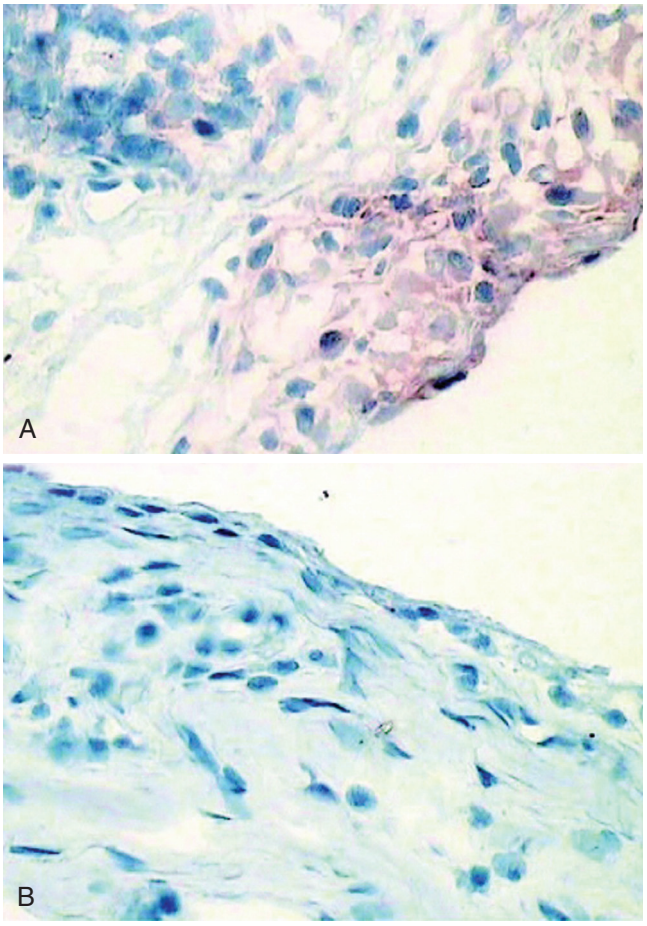

**Figure 69-15** Phospho-STAT1 expression in rheumatoid arthritis synovium. Signal transducer and activator of transcription (STAT)1 is a transcription factor activated by the Janus kinases that regulates interferon responses. **A,** Expression of STAT1 in the synovial intimal lining using immunohistochemistry. **B,** A synovial biopsy from the same patient after treatment with a traditional disease-modifying anti-rheumatic drug. Note that expression markedly decreased after therapy. *(From Walker JG, Ahern MJ, Coleman M, et al: Changes in synovial tissue Jak-STAT expression in rheumatoid arthritis in response to successful DMARD treatment.* Ann Rheum Dis *65:1558, 2006.)*

arthritis. Mice with collagen-induced arthritis that are injected with IFN-β or transduced fibroblasts expressing IFN-β have less severe disease compared with control subjects, including decreased bone and cartilage destruction. As previously noted, a clinical trial of IFN-β in RA showed no benefit, possibly because IFN acts by increasing IL-1Ra. An alternative approach might be to inhibit IKK-related kinases to block the chemokines associated with the IFN response and concomitantly provide treatment with low levels of exogenous IFN-β.[213]

### Spleen Tyrosine Kinase

Several other signaling molecules have been implicated in RA and are potential therapeutic targets. For example, Syk is involved in immunoreceptor signaling in a variety of cell types and plays a critical role in Fc receptor signaling in macrophages and mast cells. It also participates in B cell activation after ligation of the B cell receptor. A small molecule Syk inhibitor has demonstrated efficacy in patients with RA, although the compound fostamatinib also blocks many other kinases.[214] Phase III studies with this compound only showed modest efficacy (ACR20 response rates around 40%) without disease-modifying effect.

### PI3 Kinases and Other Signaling Pathways

The PI3Ks, especially the δ and γ isoforms, are also attractive therapeutic targets because of their role in innate immunity and cell recruitment, respectively. As previously noted, PI3Kγ is the convergence point for chemokine signaling and could permit targeting of several chemoattractants with a single compound. The δ isoform is notable because it not only regulates FLS invasion but also is required for B cell differentiation and activation. Therefore, PI3Kδ is an alternative way to target B cells. Bruton's tyrosine kinase (BTK) inhibitors represent another kinase that can be blocked to suppress B cells as well as innate immune response in myeloid cells. c-Kit blockade has also been evaluated in an open-label study that provided a positive signal. There is no shortage of targets, and many others, including upstream MAP kinase regulators, Ras, IL-1–associated kinases (IRAKs), and sphingosine kinase-1 (SK-1), will be evaluated in the future for a variety of immune-mediated diseases.

## CELL SURVIVAL AND DEATH IN RHEUMATOID SYNOVIUM

**KEY POINTS**

- **Reactive oxygen and nitrogen in RA joints contribute to a toxic environment that can damage cells and increase inflammation.**
- **Inadequate apoptosis, or cell death, can contribute to the accumulation of cells in rheumatoid synovium.**
- **Abnormalities of key regulatory genes such as the p53 tumor suppressor can enhance accumulation of cells in the joint.**
- **Inducing apoptosis can potentially suppress synovial inflammation and joint destruction.**

Studies defining the life cycle of cells have opened a new door to understanding the pathogenesis of neoplastic and inflammatory diseases. In this section, the role of oxidative damage, programmed cell death, and permanent changes in the genome are discussed because they can alter the natural history of RA.

### Reactive Oxygen and Nitrogen

Oxidative stress in the joints of patients with RA results from increased pressure in the synovial cavity, reduced capillary density, vascular changes, an increased metabolic rate of synovial tissue, and locally activated leukocytes. The generation of reactive oxygen species can also be facilitated by repetitive ischemia-reperfusion injury in the joint. Tissue injury releases iron and copper ions and heme proteins that are catalytic for free-radical reactions. Electron transport chains are also disrupted in the mitochondria and endoplasmic reticulum, leading to leakage of electrons to form superoxide.

Increased reactive oxygen species in patients with RA leads to elevated levels of lipid peroxidation products, degradation of hyaluronic acid by free radicals, decreased levels of ascorbic acid in serum and synovial fluid, and increased breath pentane excretion. The levels of thioredoxin, a marker of oxidative stress, are also significantly higher in synovial fluid from patients with RA compared with other forms of arthritis. Peripheral blood lymphocyte DNA from patients with RA contains significantly increased levels of the mutagenic 8-oxohydrodeoxyguanosine, which is a product of oxidative damage to DNA, pointing to the genotoxic effects of oxidative stress.

NO production is also high in rheumatoid synovial tissue. Low levels of NO are constitutively produced by endothelial or neuronal NO synthases, and enzyme levels are substantially increased by inducible NO synthase after stimulation by cytokines or bacterial products. Nitrite levels in synovial fluid are elevated in patients with RA, indicating local NO production. In addition, the urinary nitrate-to-creatinine ratio is increased and inducible NO synthase is present in the synovium.

### Apoptosis and Autophagy

Programmed cell death, or apoptosis, removes cells safely from living tissue and permits remodeling, or cell deletion, without causing an inflammatory response. Apoptosis is a normal process that is tightly regulated and can be initiated by withdrawal of hormones and growth factors. Autophagy represents an alternative adaptive mechanism for cell survival that breaks down some cellular components through lysosomes and maintains critical functions to ensure that the cell does not die.

#### Genes Regulating Apoptosis

The accumulation of cells in RA results from a balance of cell recruitment, cell egress, local proliferation, and local death. Any imbalance can potentially lead to synovial hyperplasia. T cell apoptosis in RA synovial effusions, for instance, is significantly less than lymphocytes from crystal-induced arthropathy. High expression of the anti-apoptotic

molecule Bcl-2 is found in lymphoid aggregates and protects synovial T cells from programmed cell death. Resistance to apoptosis in vitro increases if RA T cells are co-cultured with FLS. The specific adhesion molecules involved are not defined, although the integrin-binding RGD motif (arginine-glycine-asparagine) blocks the protective effects of synoviocytes.

Fas and its TNF superfamily counter-receptor Fas ligand (FasL) are potent regulators of cell death for many cell types, including synovial T cells and synoviocytes. Fas is expressed by rheumatoid synovial fluid T cells, and the number of $Fas^+$ cells in the peripheral blood of patients with RA is greater than in healthy control subjects.[215] Anti-Fas antibody, which cross-links Fas on cell surfaces, rapidly causes apoptosis in synovial fluid B and T lymphocytes in RA, although peripheral-blood T cells are more resistant. Another member of the TNF superfamily, TNF-related apoptosis-inducing ligand (TRAIL), binds to two receptors (DR4 or DR5) to induce caspase-dependent apoptosis. DR5 is expressed in RA FLS but not OA cells, and apoptosis can be induced by either TRAIL or agonistic anti-DR5 antibody.[216]

Studies of apoptosis in RA synovial tissue show only a small number of apoptotic nuclei in the intimal lining and sublining.[217] Electron microscopic studies show rare cells that exhibit the typical findings of programmed cell death. Lymphoid aggregates containing high levels of Bcl-2 have few apoptotic cells. Macrophage apoptosis is also low because they express high levels of the caspase 8 inhibitor FLICE-like inhibitory protein (FLIP), which can inhibit Fas-mediated apoptosis.

It is comparatively difficult to induce apoptosis in synoviocytes through a variety of mechanisms, including Fas ligation. p53, which typically induces cell-cycle arrest and either DNA repair or apoptosis, is also expressed in the synovial lining and sublining. However, one of the main effectors of p53-mediated apoptosis, p53 upregulated modulator of apoptosis (PUMA), is present only in low concentrations in the synovium and cultured synoviocytes. Synoviocytes are resistant to p53-mediated apoptosis even when cells are forced to overexpress the protein using genetic methods.[218] Synoviocyte apoptosis can be initiated by oxidative stress such as hydrogen peroxide or by exposure to NO.

The relative paucity of apoptosis in RA can also be partially explained by patterns of gene expression that favor cell survival. Recently, the protease ADAM15 was implicated in FLS resistance induced by FasL through activation of the focal adhesion kinase pathway.[219] It is of interest that many other genes in same pathway are differentially methylated and could also increase resistance to cell death.[220] Sentrin-1, a ubiquitin-like protein, regulates the cell survival by modifying proteins involved in apoptosis. Sentrin-1 is expressed in RA synovium, especially at sites of cartilage invasion, and protects cells from Fas-mediated death. A second protein, phosphatase and tensin homolog on chromosome 10 (PTEN), was originally defined as a key factor that protects against tumorigenesis through antagonism of PI3K, Akt, and many other proliferative pathways. Underexpression of PTEN in RA has been described in rheumatoid synovial intimal lining, as well as cultured FLS.[221]

### Genes Regulating Autophagy

Genes associated with increased autophagy, such as LC3 and Beclin-1 and the miRNA miR-30a, are increased in the RA synovial intimal lining compared with OA synovium.[222] These genes might program cells for improved survival through autophagy rather than cell death through apoptosis. In RA FLS, induction of autophagy by inhibiting proteasome-mediated protein degradation protected against cell death, whereas endoplasmic reticulum stress increased apoptosis. Therefore, the degree to which autophagy regulates cell survival is context-specific, and conclusions on its role in synovitis remain unclear.

### Possible Therapeutic Interventions that Increase Apoptosis

Fas-induced death has been used successfully in murine collagen-induced arthritis using anti-Fas antibodies and adenovirus encoding for Fas ligand. Anti-Fas antibody also induces synovial cell death in RA synovial tissue explanted in SCID mice. In the SCID mouse model using RA synovial explants, anti-DR5 antibody decreased cartilage erosion. Similarly, adenoviral transfer of TRAIL in a rabbit model of arthritis decreases synovial inflammation.[223] The importance of apoptosis as a regulator of inflammation was confirmed in murine collagen-induced arthritis, where genetic DR5 deficiency exacerbated the disease. Blocking Foxo3a in PMNs is also an effective method of deleting these inflammatory cells and suppressing inflammatory arthritis in mice.[147]

The Bcl-2 homology 3 (BH3) domain-only proteins are potent inducers of apoptosis. The challenge is how to get these proteins expressed in the target cell.[224] One of these proteins, Bim, was engineered into a cell membrane permeable protein (TAT-Bim) and evaluated in the passive K/BxN model. The construct decreased arthritis severity in prophylactic and therapeutic treatment protocols and was associated with apoptosis of cells, mainly in the myeloid lineage. Therefore, targeted cell death of individual lineages can potentially decrease inflammatory arthritis.

Other molecules that regulate apoptosis have also demonstrated potential utility in animal models. For instance, NF-κB blockade in streptococcal cell-wall arthritis induces synovial apoptosis and suppresses arthritis. *TP53* gene therapy in rabbit antigen-induced arthritis induces synovial apoptosis and decreases inflammation.[225] The pleiotropic activities of p53 were demonstrated in collagen-induced arthritis because $Tp53^{-/-}$ mice with the disease developed increased inflammation and greater joint destruction in association with decreased apoptosis. Joint damage was mediated by increased expression of collagenase genes in the knockout mice, most likely because p53 directly suppresses MMP gene transcription.[226]

### Tumor Suppressor Genes

The p53 tumor suppressor is a key regulator of DNA repair and cell replication. p53 protein expression is significantly greater in the rheumatoid synovium compared with OA and normal tissue.[227] It is of interest that p53 protein can also

be detected in RA synovium from patients with very early stage RA. However, its expression is much lower in other inflammatory arthropathies such as reactive arthritis, which might reflect greater DNA damage and oxidative stress in RA.

Somatic mutations in the *TP53* gene, which encodes p53, that can occur in RA synovium could contribute to the unusual phenotype of RA synoviocytes and inadequate apoptosis in synovial tissue.[228] Transition mutations, which are characteristic of damage induced by reactive oxygen or NO, account for more than 80% of the base changes. Some of the mutant *TP53* genes exhibit dominant negative characteristics and suppress the function of the wild-type allele. Microdissection studies identified mutant islands with oligoclonal expansion, and the loss of p53 function in a region of RA synovium was associated with increased IL-6 gene expression in the same location. The data suggest that mutations do not cause RA but, instead, are the result of long-standing oxidative stress. The gene alterations can then potentially increase the aggressive nature of the synovium and alter the natural history of RA. *TP53* also regulates T cell differentiation through a STAT-mediated mechanism. Decreased STAT5 in $CD4^+$ T cells in p53-deficient mice have increased Th17 and decreased Treg function.[229] These data suggest yet another role for this tumor suppressor gene in immune-mediated diseases.

Abnormalities in other genes have also been reported in RA. For instance, synovial T cells in RA have an increased incidence of mutations in the *HPRT1* gene. Although not functionally important, these synovial T cells act as a marker for oxidative damage that occurs in the synovial milieu. Some of these abnormal lymphocytes can also be detected in the peripheral blood, suggesting that articular T cells can migrate out of the joint. Mutations in mitochondrial genes have been described in synoviocytes.

## BLOOD VESSELS AND THE SYNOVIAL VASCULATURE

**KEY POINTS**

- **The synovium in RA is a hypoxic environment.**
- **Angiogenesis is a dynamic process in RA that provides nutrients to expanding synovium.**
- **Angiogenic factors such as IL-8, FGF, and vascular endothelial growth factor can enhance blood vessel proliferation in the synovium.**
- **Microvascular endothelial cells in the synovium express adhesion molecules that guide circulating cells into the joint under the influence of chemoattractants.**

Blood vessels play an active role in such inflammatory processes, not only as a means of selecting which cells should enter the tissue, but also as a determinant of tissue growth and nutrition through the proliferation of new capillaries. Understanding the structure and function of the microvasculature provides insights into how a highly catabolic tissue such as the rheumatoid synovium can flourish.

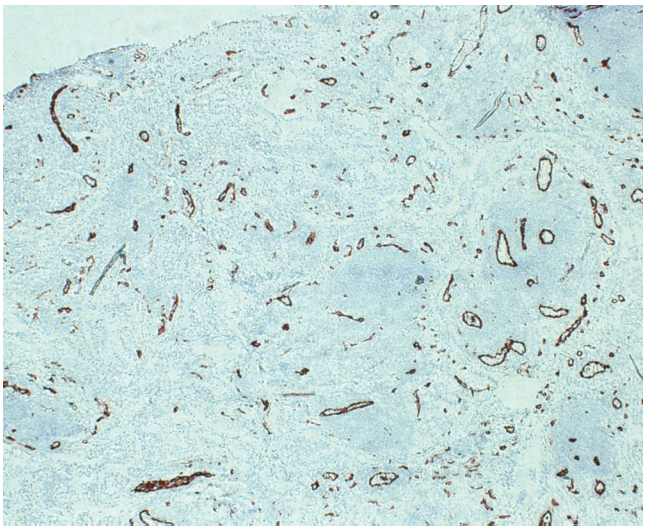

**Figure 69-16** Human rheumatoid synovial membrane stained with antibody to von Willebrand factor to delineate blood vessels. Virtually all of these blood vessels formed in response to angiogenic stimuli after the rheumatoid synovitis had been initiated. *(Courtesy Dr. Paul-Peter Tak.)*

### Angiogenesis: Feeding the Starved Synovium

The importance of luxurious new capillary growth early in the development of synovitis has been recognized for many years. The absolute number of blood vessels is increased in RA synovium (Figure 69-16), with a rich network of sublining capillaries and postcapillary venules in histologic sections stained with endothelium-specific antibodies. These blood vessels are not necessarily normal, however, with a predominance of straight, branching morphologic features compared with tortuous vessels in psoriatic arthritis synovium. The blood vessels in the inflamed synovium are less mature, probably as a result of increased DNA damage and decreased recruitment of pericytes. It is of interest that the immature vasculature is selectively depleted by TNF blockers in RA.[230]

#### Hypoxia

The mass of tissue outstrips angiogenesis in RA as determined by the number of blood vessels per unit area and causes local tissue ischemia.[231] Synovial fluid oxygen tensions are remarkably low, lactate measurements are frequently high, and the pH can be as low as 6.8 in extreme circumstances. The mean rheumatoid synovial fluid pressure of oxygen in the blood ($pO_2$) in samples from rheumatoid knees is approximately 30 mm Hg and occasionally less than 15 mm Hg. Another cause of diminished blood flow is increased positive pressure exerted by synovial effusions within the joint, a process that obliterates capillary flow while producing ischemia-reperfusion injury in the joint. Altered vascular flow may not be the only cause of hypoxia in joints; oxygen consumption of the rheumatoid synovium is 20 times normal.

Hypoxia is a potent stimulus for angiogenesis, and many angiogenic factors are regulated by the hypoxia-sensing protein hypoxia-inducible factor (HIF)-1α. Low oxygen

tension also leads to HIF-1α–induced transcription of VEGF, a specific endothelial cell mitogen that is present in high concentrations in rheumatoid synovial fluid and tissue. Elevated serum concentrations in early disease correlate with subsequent radiographic progress. VEGF also stimulates expression of collagenase, which can degrade the extra-cellular matrix to make room for the advancing vasculature and pannus. VEGF expression is especially high in the synovial intimal lining, and the angiogenesis factor is also produced by cultured FLS that have been exposed to hypoxia and IL-1. HIF-1α has other functions that regulate inflammation; selective deficiency in myeloid lineage cells suppresses inflammation in the passive K/BxN model of arthritis.[232]

HIF-1α regulates a number of other pathways that can modify inflammation and blood vessel formation. For example, it induces the alarmin IL-33 in RA FLS, creating a novel regulatory circuit that connects hypoxia to innate immune responses.[233] HIF-1α also activates STAT3, mimicking some of the sequelae of IL-6 stimulation.[234] Blocking HIF-1α in rheumatoid synovial explants decreases production of IL-6, IL-8, and MMP3. These data suggest that hypoxia not only drives blood vessel proliferation but also cytokine expression and matrix destruction.

### Angiogenic Factors

VEGF can bind to two receptors with tyrosine kinase domains: VEGF-R1/Flt-1 and VEGF-R2. VEGF-R1 regulates inflammatory responses in macrophages such as IL-6 and phagocytosis. Small-molecule VEGF-R inhibitors also suppress acute models of inflammation. Therefore, targeting this receptor with a small molecule might suppress the angiogenic and pro-inflammatory actions of VEGF.

In addition to the hypoxia-driven stimulus for blood vessel growth, the inflammatory cytokine milieu of the joint also encourages angiogenesis. Several pro-inflammatory factors expressed by the rheumatoid joint, including IL-8, FGF, and TNF, are angiogenic. Many of these cytokines further enhance angiogenesis by increasing expression of angiopoietins (Ang-1 and Ang-2) by synoviocytes, which can then bind to their tyrosine kinase receptor, Tie-1, on RA capillary endothelial cells. Co-expression of Tie-1 and Ang-1 in early undifferentiated arthritis correlates with the development of RA.[235] Additional angiogenesis factors derived from activated adhesion molecules on the surface of endothelial cells, such as soluble E-selectin and soluble VCAM, are released in RA synovium and contribute to vascular proliferation.[236] Limited quantities of some anti-angiogenic mediators that inhibit capillary proliferation, such as platelet factor-4 and thrombospondin, are also produced by the joint. Other pathways and factors that contribute to blood vessel formation in RA synovium include TLR5 ligation and expression of the fucosyl transferase Fut1.[237]

Vascular remodeling is an active process that involves the continuous creation and resorption of blood vessels. In RA, new capillaries that form under the influence of pro-angiogenic factors can be identified by the expression of integrins such as $\alpha_v\beta_3$. Endothelial proliferation is especially prominent in synovial tissue regions containing VEGF. Synovial blood vessel involution also can be detected as evidenced by apoptosis of the endothelium in other synovial locations. The ratio of proliferating and involuting blood vessels is significantly higher in RA than in OA or normal synovium.

### Targeting Angiogenesis

The importance of new blood-vessel formation in inflammatory arthritis was elegantly demonstrated in the collagen-induced arthritis model. The disease was markedly attenuated in animals pretreated with an angiostatic compound similar to fumagillin, which is derived from *Aspergillus*.[238] This compound is cytotoxic to proliferating, but not resting, endothelial cells. In addition, established arthritis regressed if treatment was initiated well into the course of the disease. Hence angiogenesis is essential for the establishment and progression of inflammatory arthritis because of the need for blood vessels to either recruit leukocytes or provide nutrients and oxygen to starved tissue.

Targeting HIF-1α with a small molecule inhibitor that blocks nuclear translocation and VEGF induction was effective in adjuvant arthritis.[239] Other small molecule inhibitors of the VEGF-R1 with either antibodies or kinase inhibitors have been successfully tested in pre-clinical models of arthritis as well. One of these, vatalanib, decreased inflammatory knee arthritis in rabbits.

Several other anti-angiogenesis approaches are effective in animal models of arthritis. For instance, gene therapy with NK4, which is a hepatocyte growth factor antagonist, inhibits angiogenesis and inflammatory arthritis in murine models.[240] Thrombospondin 1 overexpression significantly decreased blood vessel density, inflammation, and joint destruction in rat collagen-induced arthritis. Direct intra-articular administration of a cyclic RGD peptide was used in a rabbit model to block $\alpha_v\beta_3$ integrin.[241] The cyclic peptide decreased joint inflammation, increased endothelial cell apoptosis, and suppressed bone and cartilage destruction.

The ability of RGD to bind selectively to proliferating blood vessels was also used to direct a proapoptotic agent to synovial neovasculature in murine collagen-induced arthritis.[242] The cyclic RGD peptide was administered systemically and accumulated in inflamed synovium but not in normal joints or other organs. Apoptosis was induced in synovial blood vessels, and arthritis regressed. The potent angiogenesis inhibitor endostatin has been tested in the SCID mouse model, and it decreased synovial explant inflammatory cell infiltration and capillary density. Despite the compelling rationale for anti-angiogenic therapy, an anti-$\alpha_v$ antibody showed minimal efficacy in a clinical trial, perhaps because other pathways are more important in the synovium.

## Adhesion Molecule Regulation

Endothelial cells activated by cytokines and other mediators express adhesion molecules that bind to counter-receptors on mononuclear cells and neutrophils from the circulation and facilitate their recruitment from the blood (see Chapter 25). Several categories of vascular adhesion molecules exist. The selectins (E-, L-, and P-selectin) are a family of adhesion molecules whose primary ligands are

carbohydrates, especially sialyl LewisX, and related oligosaccharides. The selectins are expressed by RA synovial endothelial cells, which can initiate the influx of blood cells into the joint. A second family is integrins, which are heterodimers that include an α and a β chain. The counter-receptors depend on the specific combination of these chains and are frequently proteins in the immunoglobulin supergene family or extra-cellular matrix proteins.

### Integrins and Their Ligands

As one might expect, adhesion molecule expression is increased in the RA synovium as a result of the rich cytokine milieu. Immunohistochemical techniques localize high levels of ICAM-1 to sublining macrophages, macrophage-like synovial lining cells, and fibroblasts compared with normal tissue.[243] Significant amounts are also present on the majority of vascular endothelial cells. Cultured FLS also constitutively express ICAM-1, which can be markedly increased by TNF, IL-1, and IFN-γ. ICAM-1 and the other ICAM family members can bind to cells expressing the β2 integrins, especially neutrophils.

Adhesion of $\alpha_4\beta_1$(VLA-4)–expressing mononuclear cells such as memory T cells or monocytes to cytokine-activated endothelial cells can be mediated by VCAM-1 or CS-1 fibronectin. A role for VLA-4 in arthritis has been suggested by a number of experimental observations. In adjuvant arthritis in rats, anti-$\alpha_4$ antibody decreases lymphocyte accumulation in the joint but not in lymph nodes, suggesting that VLA-4 is more important in recruitment to inflamed sites than to non-inflamed sites.[244] T lymphocytes isolated from the synovial fluid and synovial membrane of patients with RA exhibit increased VLA-4–mediated adherence to VCAM-1, relative to autologous peripheral blood lymphocytes. These studies also suggest that leukocytes expressing functionally activated VLA-4 are selectively recruited to inflammatory sites in RA. Anti–VLA-4 antibody, which is effective in multiple sclerosis, has potential utility in RA, but enthusiasm is mitigated by effects on host defense observed with natalizumab.

Moderate amounts of VCAM-1 are expressed in RA synovial blood vessels. Surprisingly, the intimal lining is the location of the most intense staining with anti–VCAM-1 antibodies on histologic sections. Even normal synovial tissue expresses VCAM-1 in the lining, albeit less than in RA. Cultured FLS constitutively express small amounts of VCAM-1, and the level is increased by a variety of macrophage and T cell–derived cytokines. VCAM-1 also contributes to T cell adhesion to high endothelial venules in frozen sections of RA synovium.[245]

The integrin $\alpha_4\beta_7$, which also binds to VCAM-1, is a specific adhesion molecule involved in lymphocyte homing to Peyer's patches. Most intraepithelial and lamina propria lymphocytes express $\alpha_4\beta_7$; this molecule is rarely identified in other lymphoid tissues. The expression of $\alpha_4\beta_7$ on peripheral blood lymphocytes from patients with RA is low (similar to normal persons), but up to a quarter of synovial fluid lymphocytes, mostly $CD8^+$ T lymphocytes, express this adhesion molecule and provide an interesting link between arthritis and the gut.[246] $\alpha_2\beta_1$, which binds to native collagen, has also been implicated in Th17 cell differentiation in mice.[247]

### Therapeutic Potential of Blocking Adhesion Molecules

The therapeutic potential for anti-adhesion therapy has been studied in the SCID mouse model. Labeled human peripheral mononuclear cells were injected into engrafted mice, and migration into the tissue was examined.[248] When the mice were treated with TNF, ICAM-1 expression and trafficking into synovium were significantly increased. Anti–ICAM-1 antibody also blocked leukocyte migration into the explant under these conditions. In another study, tonsil mononuclear cells also migrated into the RA synovial grafts in SCID mice. RA clinical trials using anti–ICAM-1 antibody or anti-sense ICAM-1 oligonucleotides produced minimal significant clinical benefit. Surprisingly, mice lacking E- and P-selectin actually had accelerated disease in the collagen-induced arthritis model. This paradoxical result serves as a reminder of the complexity of the inflammatory process.[249]

## CARTILAGE AND BONE DESTRUCTION

**KEY POINTS**

- Cartilage degradation and bone destruction in RA are mediated by distinct mechanisms and cell types.
- Several classes of proteases including metalloproteinases, serine proteases, cathepsins, and aggrecanases are produced by intimal lining cells in RA, especially FLS.
- Synovial lining cells, especially FLS, invade and damage cartilage in RA.
- Bone destruction is mediated by osteoclasts that are activated under the influence of RANKL and other cytokines produced by RA synovium.

### Cartilage Destruction and the Pannus-Cartilage Junction

Macrophage-like and fibroblast-like cells migrate onto the surface of cartilage, and the FLS in particular penetrate into cartilage matrix (Figure 69-17). This invasive "pannus" is more commonly found in metatarsophalangeal joints, compared with hip and knee joints, perhaps explaining why erosions occur more often around small joints.

FLS from the intimal lining are major effectors of cartilage destruction in RA. They produce a prodigious amount of proteases, bind to cartilage, and invade the extra-cellular matrix. The pivotal role of synoviocytes in cartilage destruction was demonstrated in arthritis models using cadherin-11 blockade to disrupt the intimal lining. Cartilage destruction is markedly attenuated, even though bone erosions progress.[250]

Other cells in the joint, including macrophages and synovial fluid neutrophils, could also be responsible for cartilage damage, whereas osteoclasts are responsible for bone erosions. More primitive mesenchymal cells isolated directly from the cartilage-pannus junction express phenotypic and functional features of both synoviocytes and chondrocytes and have also been described in the synovium.

Cartilage is destroyed in RA by both enzymatic and mechanical processes. The enzymes induced by factors such

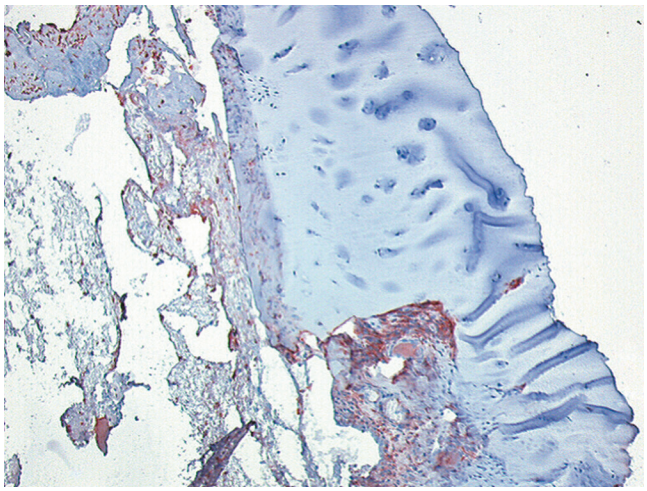

**Figure 69-17** Pannus-cartilage junction. The invasive front of pannus burrows into cartilage matrix in rheumatoid arthritis joints. The pannus is primarily composed of macrophages and mesenchymal cells. Immunostaining with anti-CD68 antibody shows the distribution of macrophages in the invasive tissue. *(Courtesy Dr. Paul-Peter Tak.)*

SERPINs, Serine protease inhibitors; TIMP, tissue inhibitor of metalloproteinases.

as IL-1, IL-17, TNF, phagocytosis of debris by synovial cells, and mechanical trauma degrade the matrix proteins. Early in synovitis, proteoglycans are depleted from the tissue, most likely as a result of the catabolic effect of cytokines such as IL-1 on chondrocytes with the production of MMPs and aggrecanases, and this depletion leads to mechanical weakening of cartilage. As proteoglycans are depleted, cartilage loses elasticity and becomes susceptible to mechanical fragmentation and fibrillation. Eventually the tissue loses functional integrity concurrent with its dissolution by collagenases and stromelysins. Some of the MMPs responsible for this process are also derived from the chondrocytes themselves. Multiple MMPs, especially stromelysin (MMP-3) and collagenases (MMP-1 and MMP-13), are expressed in RA cartilage, and in situ hybridization studies confirm the presence of the mRNA within chondrocytes.[251] Hence the cartilage is under attack from a multitude of sources: It is bathed in protease-rich synovial fluid, under extrinsic attack from the invasive pannus, damaged from within by chondrocytes, and fragmented by mechanical forces.

Enzymes released by PMNs in synovial fluid, including neutrophil collagenase and multiple serine proteases, also contribute to cartilage loss. Immune complexes containing RFs are embedded in the superficial layers of cartilage and can attract and activate neutrophils. Electron microscopic examinations of articular cartilage in RA reveal evidence of breakdown of collagen and proteoglycan as a result of superficial activity of joint fluid enzymes. In a rabbit model of arthritis in which IL-1 was injected directly into the joint, the degree of cartilage damage as measured by proteoglycan levels in synovial fluid correlated best with the stromelysin concentrations in synovial effusions (presumably derived from synoviocytes). Neutrophil depletion of animals did not interfere with subsequent destruction of extra-cellular matrix, suggesting that MMPs derived from the synovium are more important in this model.

Most animal studies suggest that IL-1 is a key regulator of matrix degradation in arthritis. Although TNF blockade has clear anti-inflammatory effects, chondroprotection is less prominent. The joint destruction observed in TNF-dependent models often requires IL-1. IL-17 and TLR ligands can also contribute to joint destruction directly or by synergizing with IL-1 and TNF.

The rate-limiting step in cartilage loss is the cleavage of collagen because proteoglycans are degraded soon after inflammation begins. MMPs, which are released into the extra-cellular space and are active at neutral pH, are probably responsible for most of the effective proteolysis of articular-cartilage proteins, but other classes of enzymes may contribute to joint destruction. Enzymes such as cathepsins B, D, G, K, L, and H may play a role inside and outside cells by degrading noncollagenous matrix proteins. Serine proteinases (e.g., elastase and plasmin) and aggrecanases can also contribute to matrix damage.

## Proteases: Mediators of Joint Destruction

### Matrix Metalloproteinases

The MMPs are a family of enzymes that participate in extra-cellular matrix degradation and remodeling (see Chapter 8). They are usually secreted as inactive proenzymes, and their proteolytic activity requires limited cleavage or denaturation to reveal a zinc cation at the core. Their activation can be mediated by other proteases, including trypsin, plasmin, or tryptase. The substrates for MMPs are varied but quite specific for individual members of the family. Collagenases degrade native collagen, whereas gelatinases are able to degrade denatured or cleaved collagen. Stromelysins have broader specificity and can digest proteoglycans in addition to proteins. They also process procollagenase to the active form, thereby serving as a positive-feedback signal for matrix destruction. Some MMPs such as TNF convertase (TACE) are responsible for the processing and release of cytokines from the cell surface. Many different families of proteinases are found in the joint (Table 69-6), but the MMPs are thought to play a pivotal role in joint destruction.

**Regulation of MMP Production.** The cytokine milieu has the capacity to induce the biosynthesis of MMPs by synovial cells and alter the balance between extra-cellular matrix production and degradation. IL-1 and TNF, in particular, induce MMP gene expression by many cells, especially FLS and chondrocytes. The two cytokines are additive or synergistic when used in combination. Many other cytokines and TLR ligands implicated in rheumatoid synovitis can also induce MMP expression, including IL-17, LIF, LPS, and peptidoglycans.

Culture medium from rheumatoid synovium stimulates cartilage degradation in vitro, mainly because IL-1 stimulates MMP production by synovial intimal lining cells. IL-6 does not induce MMP production by synovial cells but instead increases the production of TIMP-1, a naturally occurring inhibitor of MMPs. TGF-β inhibits collagenase synthesis and enhances the production of TIMP by fibroblasts and chondrocytes. TGF-β also increases collagen production, shifting the balance from destruction to matrix repair. Thus regulation of matrix degradation is a balance between matrix production, protease production and activation, and endogenous inhibitors that inactivate the proteases.

Although multiple upstream regulatory sequences are involved in MMP gene transcription, the dominant element in the promoter is AP-1. Other regulatory sites such as an NF-κB–like region can also contribute to collagenase expression. AP-1 activity is markedly increased in FLS by pro-inflammatory cytokines such as IL-1, TNF, and IL-17, and its transcriptional activity is mediated by increased expression of components such as c-Jun. The MAP kinases are especially important for this activity, and JNK is the most efficient upstream activator. Glucocorticoids markedly inhibit MMP gene expression by blocking AP-1. Engagement of cadherin 11 on the surface of FLS can also increase MMP expression, with associated increases in MAP kinase and NF-κB activation.[252]

Collagenases and stromelysins have the capacity to degrade virtually all the important structural proteins in the extra-cellular tissues within joints. Collagenase-1 (MMP-1) cleaves through the triple-helical collagen molecule at a single glycine-isoleucine bond approximately three-quarters of the distance from the $NH_2$-terminus. This enzyme degrades only the interstitial helical collagens (e.g., types I, II, III, and X). It has little or no activity against types IV, V, and IX and other nonhelical collagens or denatured collagen; the degradation of the latter is primarily accomplished by the gelatinases. MMP-1, however, is a relatively inefficient enzyme, whereas collagenase-3 (MMP-13) has more favorable kinetics. Neutrophil collagenase, or MMP-8, is constitutively stored in neutrophil granules and is released into the milieu after degranulation.

**MMP Expression in Synovium.** The collagenase-1 and collagenase-3 genes are produced by RA synovial tissue, and the latter is highly expressed by chondrocytes in cartilage. In situ hybridization studies show that the primary location of collagenase-1 gene expression in the synovium, like many other MMPs, is the intimal lining, especially in FLS.[253] Subchondral bone is another region in which proteinase expression occurs in RA and could participate in bone resorption. Increased MMP gene expression is an early feature of RA and occurs during the first few weeks of clinically active disease. High expression of collagenase-1, as well as gelatinases such as MMP-2, early in the disease process correlates with rapidly progressive erosions. Similarly, increased blood levels of the proenzymes are also associated with more severe disease.

Stromelysin-1 (MMP-3) and the other members of the stromelysin family effectively degrade type IV collagen, fibronectin, laminin, proteoglycan core protein, and type IX collagen. Stromelysin removes the $NH_2$-terminal propeptides from type I procollagen and can activate procollagenase, creating a positive feedback loop that amplifies damage. Like collagenase, stromelysin gene expression occurs mainly in the synovial intimal lining (Figure 69-18). Despite the putative importance of this enzyme in matrix destruction, stromelysin knockout mice are susceptible to collagen-induced arthritis and develop as much joint destruction as mice with functional stromelysin.[254] This observation substantially decreased interest in stromelysin inhibitors to treat diseases such as RA.

MMP inhibitors are effective in animal models of RA and can suppress bone destruction, as well as the inflammatory synovitis. In models of OA, deletion of MMP genes such as stromelysin does not necessarily improve outcomes. Clinical trials in RA using nonselective inhibitors have had minimal success and significant adverse effects, possibly related to decreased matrix turnover. TACE inhibitors can unexpectedly increase disease severity in RA, perhaps as a result of higher levels of membrane-bound TNF. One of the most consistent adverse effects experienced by patients treated with MMP inhibitors is increased joint stiffness, which is thought to result from deposition of fibrous tissue without sufficient protease activity to permit removal of matrix proteins.

### Cysteine Proteases: The Cathepsins

Cathepsins are an extensive family of cysteine proteases that have broad proteolytic activity, including activity on types II, IX, and XI collagen and proteoglycans. Like MMPs, the cathepsins are regulated by cytokines and by proto-oncogenes such as Ras. IL-1 and TNF induce cathepsin L expression in cultured FLS.[255] In situ hybridization studies demonstrate cathepsin B and L RNA transcripts in RA synovium, especially at sites of erosion. A ribozyme that cleaves cathepsin L decreases FLS invasion and cartilage destruction in the SCID mouse model with implanted cultured synoviocytes, which suggests that this protease has clinical relevance.

Cathepsin K has been implicated in bone resorption by osteoclasts. This protease is unique among the cathepsins because it can degrade native type I collagen. It is expressed in RA synovial tissue by both macrophages and fibroblasts and is present in significantly higher concentrations than in OA.[256] Serum levels of cathepsin K correlate with the extent of radiographic damage. A potential role of cathepsins as mediators of bone destruction in arthritis was confirmed in studies in which cysteine protease inhibitors significantly decrease joint damage in the rodent arthritis models. In the TNF-transgenic mouse model, cathepsin K deficiency decreased, but did not eliminate, bone erosions.[257]

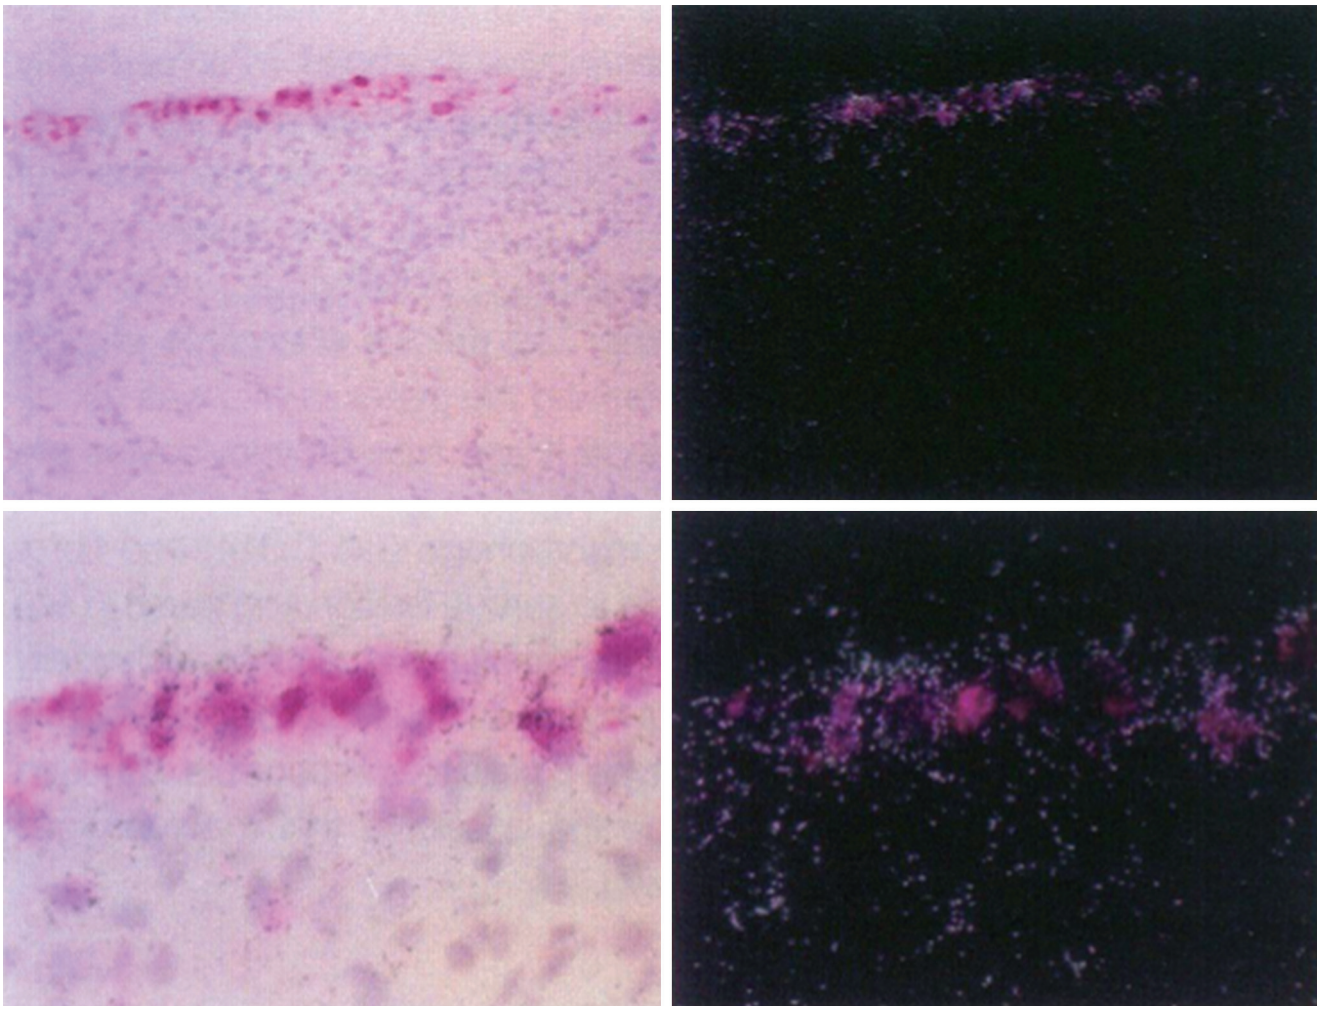

**Figure 69-18** Localization of stromelysin and tissue inhibitor of metalloproteinases-1 (TIMP-1) in rheumatoid arthritis (RA) synovial tissue by in situ hybridization. Stromelysin mRNA *(pink color)* is mainly expressed in the synovial intimal lining, presumably by cytokine-stimulated type B synoviocytes. TIMP mRNA is shown by silver granules in the same region, best viewed in the dark-field view where the silver grains appear as bright granules *(right panels)*. High and low power views of the same field are shown. *(From Paine MM, Firestein GS: Stromelysin and tissue inhibitor of metalloproteinases gene expression in rheumatoid arthritis synovium.* Am J Pathol *140:1309–1314, 1992.)*

### Aggrecanases

Aggrecan is a major proteoglycan component of articular cartilage. Because of its large size and negative charge, it contains a considerable amount of water, which increases compressibility. Two proteolytic sites are available on aggrecan in its globular domain. One site is susceptible to MMP cleavage, whereas the other, located 32 amino acids toward the C-terminus, is the site for cleavage by a family of enzymes known as aggrecanases. The two sites can be identified in tissues using monoclonal antibodies after cleavage when specific neoepitopes are revealed.

Normal cartilage contains a surprising amount of aggrecanase neoepitope, suggesting continuous matrix turnover. The level of aggrecanase cleavage product increases with age. Two aggrecanase genes, aggrecanase-1 and aggrecanase-2, have been cloned and are members of the "a disintegrin and metalloproteinase with thrombospondin motif" (ADAMTS) family of proteins (ADAMTS-4 and ADAMTS-5, respectively). They are expressed in OA and RA cartilage, and their proteolytic activity can be detected in synovial fluids. Especially high levels of the neoepitope are present in arthritic cartilage.[258] IL-1 increases aggrecanase expression in cartilage explants, as well as cultured chondrocytes. Aggrecanase-1 and aggrecanase-2 are constitutively expressed by RA and OA FLS and synovial tissues.[259] Aggrecanase-1, but not aggrecanse-2, is induced in synoviocytes by cytokines, especially TGF-β. Genetic deletion of aggrecanse-1 has no effect on a murine OA model, but loss of aggrecanase-2 prevents degenerative changes.[260]

## Endogenous Protease Inhibitors

$\alpha_2$-Macroglobulin ($\alpha_2$M) accounts for more than 95% of collagenase inhibitory capacity in serum. The mechanism of inhibition by $\alpha_2$M involves hydrolysis by the proteinase of a susceptible region in one of the four polypeptide chains of $\alpha_2$M (sometimes called the "bait"), with subsequent trapping of the proteins within the interstices of the $\alpha_2$M. Ultimately, the protease is covalently linked to a portion of the $\alpha_2$M molecule. The serine protease inhibitors (SERPINs) are also abundant in synovial effusions and

plasma and can serve a dual purpose of directly blocking serine protease function and indirectly decreasing MMP activity by preventing serine proteases from activating MMP proenzymes. One SERPIN, $\alpha_1$–anti-trypsin, has been well characterized in synovial fluid and is frequently inactivated after oxidation by reactive oxygen species. Fibronectin also inhibits aggrecanase-1 (ADAMTS-4).[261] However, citrullinated fibronectin is much less efficient and increases aggrecanase activity, representing another potential pathogenic effect of protein citrullination in RA.

A family of proteins that specifically block MMP activity, called TIMPs, is probably the most important physiologic inhibitor in the inflamed joint. The TIMP proteins block proteinase activity by binding directly to MMPs in a 1:1 molar ratio. TIMP generally binds only to the active enzyme, although exceptions such as TIMP-2 can interact with a progelatinase (MMP-2). The inhibitors bind to MMPs with extremely high avidity. Even though the interaction does not result in new covalent bonds, it is essentially irreversible.

TIMP proteins are present in RA synovial fluid in excess. It is, in fact, difficult to detect free active collagenase and stromelysin because they are quickly bound by the inhibitors after they are activated by limited proteolysis. Immunohistochemical and in situ hybridization studies have localized the TIMPs in hyperplastic synovial lining cells in rheumatoid synovium, but not in the cells of normal synovium. TIMP gene expression is not significantly altered by IL-1 or TNF but is increased by IL-6, oncostatin M, and TGF-β. Not all effects of TIMPs are beneficial in inflammation. For instance, TIMP-3 knockout mice have significantly more synovitis and TNF production in antigen-induced arthritis, perhaps because it is not available to inhibit TACE. Similarly, TIMP-1 or TIMP-3 gene transfer limits rheumatoid FLS invasion into cartilage in an SCID mouse model. The function of these genes can extend beyond protease inhibition and include a number of paracrine functions, as well as induction of apoptosis when expressed intra-cellularly in cultured synoviocytes.

Given the important role of MMPs in tissue destruction, the relative balance between MMPs and TIMPs ultimately determines the fate of the extra-cellular matrix. The ratio in RA, with its more destructive potential, favors degradation, whereas OA has a lower MMP-to-TIMP ratio. The levels of TIMP gene expression are similar in the two diseases and may well be maximal. The higher ratio in RA results from increased MMP production. The balance between protease and inhibitor can potentially be modified in vivo with drug therapy. For instance, methotrexate therapy decreases collagenase but not TIMP-1 mRNA, which could be one mechanism of decreased joint damage in patients treated with this agent.[262]

## Regulation of Bone Destruction

Marginal erosions are the most characteristic location for bone damage in RA, especially in metacarpal phalangeal joints and proximal interphalageal joints, which traditionally has been ascribed to a "bare area" where cartilage does not protect the underlying bone from invasive pannus.[263] However, anatomic pathology and computed tomography studies suggest that erosions actually occur near collateral ligaments in these small joints where microdamage was observed in cadaveric studies. It is possible that local factors related to stress are more important than the anatomic location of overlying cartilage.[263a]

Osteoclasts are the major cells responsible for bone degradation. RANKL, which was originally described for its role in T cell–DC interactions, as well as in lymphocyte and lymph node development, is perhaps the single most important factor that modulates bone resorption. Osteoclast development is complex and involves the differentiation of monocytes under the influence of cytokines such as M-CSF in combination with RANKL. Subsequent osteoclast activation can involve several pathways, most of which also depend on the presence of RANKL. Its receptor, known as RANK, is expressed by the osteoclast precursors. RANKL is produced by many cell types, including activated T cells and FLS.

Abundant evidence implicates this powerful mechanism in bone destruction caused by inflammatory arthritis. For instance, administration of OPG, a RANKL decoy receptor, to rats with adjuvant arthritis inhibits bone destruction but has almost no effect on inflammation or clinical signs of arthritis.[264] $RANKL^{-/-}$ mice are also protected from bone erosions in the passive K/BxN model of arthritis, although cartilage destruction still occurs. Animal models of arthritis point to IL-17 as a mediator of osteoclast generation. Genetic deficiency of IL-17 or anti–IL-17 antibodies have remarkable bone-sparing effects in these experiments.

RANK, RANKL, and OPG (as well as M-CSF and IL-17) have been detected in the synovium and synovial fluid of patients with RA. The ratio of RANKL to OPG is significantly higher in RA synovial effusions than in either OA or gout, which is consistent with the more destructive nature of RA. Osteoclasts expressing tartrate-resistant acid phosphatase (TRAP), which is capable of forming resorption lacunae, can be generated from cultured RA synovial cells (Figure 69-19). This activity is blocked by the addition of exogenous OPG. RA synoviocytes and synovial

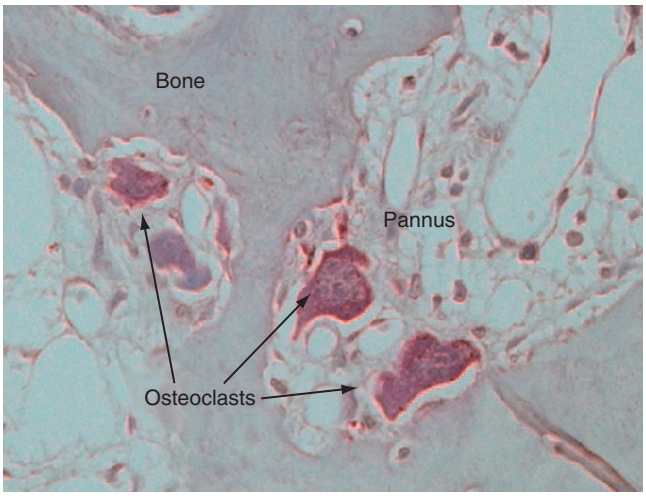

**Figure 69-19** Tartrate resistant acid phosphatase–positive osteoclasts are shown invading bone in rheumatoid arthritis (see *arrows* for examples). This process is regulated by receptor activator of NF-κB ligand (RANKL) in the presence of other cytokines such as macrophage colony-stimulating factor and TNF. *(Courtesy Dr. Steven Goldring, Dr. Ellen Gravallese, and Dr. Allison Pettit.)*

membrane T cells that display RANKL can also induce differentiation of osteoclasts from peripheral blood cells.[265]

The functional relevance of the RANK-RANKL system was confirmed in RA studies in which the anti-RANKL antibody denosumab decreased bone erosions. As predicted from animal model studies, the antibody had no effect on inflammation or clinical signs of synovitis.[266]

A second system that regulates bone remodeling involves the Wnt proteins, which regulate the balance between bone damage caused by osteoclasts and bone formation by osteoblasts. Several members of this family bind to receptors that regulate osteoblast differentiation through effects on β-catenin. Wnt signaling is modulated by many other proteins, most notably the Dickkopf (DKK) family. DKK-1 in particular blocks binding of Wnts to its receptors. In TNF-transgenic mice with arthritis, bone erosions are blocked by inhibiting either TNF or DKK-1. With the latter, proliferative bone lesions such as osteophytes formed instead.[267] Therefore, DKK-1 is a master switch that determines the fate of bone in inflammatory lesions. When present, bone destruction is favored; when absent, bone formation occurs. Other factors can also stimulate osteoclastogenesis, such as IL-21, which increases bone damage in collagen-induced arthritis.[268]

### Tissue Repair

Extra-cellular matrix turnover in RA has been likened to wound healing as a result of the critical role of collagen production, proteases, and protease inhibitors. Remodeling the matrix by removing damaged proteins is a key element in early repair. Subsequently, the balance shifts to protease inhibition, production of cytokine inhibitors, removal of inflammatory cells through apoptosis, and release of anti-inflammatory eicosanoids such as lipoxins to suppress inflammation. Neutralization of oxidants via glutathione reductase or superoxide dismutase further limits tissue damage.

This process then permits either a return to normal architecture or scar formation. TGF-β, in particular, appears to play a key role in that it increases collagen deposition, suppresses MMP expression, and enhances production of the TIMPs. Although TGF-β levels in the rheumatoid joint are substantial, they are mainly in the inactive latent form and are not sufficient to overcome the impressive array of pro-inflammatory cytokines that induce protease expression. Persistent antigen-driven T cell activation, continued antibody-driven complement fixation, or activation of other cell lineages like macrophages or FLS overwhelm the negative feedback loops that attempt to restore homeostasis. Strategies to shift from tissue damage by enhancing endogenous mechanisms could suppress symptoms and enhance appropriate remodeling of the matrix to restore homeostasis.

Because the invasive rheumatoid synovium exhibits very aggressive behavior, the possibility that the tissue contains immature cells or embryonic genes that regulate repair has been explored. The embryonic growth factors from the Wnt and Fz gene families have been demonstrated in RA synovium. Normally, these proteins participate in bone marrow progenitor differentiation and limb bud mesenchyme. Wnt5a and Fz5, in particular, are markedly elevated in RA tissues and cultured synoviocytes. When normal fibroblasts are transfected with the *WNT5A* gene, cytokine expression such as IL-6 increases significantly. Anti-sense *WNT5A* and dominant negative *WNT5A* vectors diminish cytokine expression by synoviocytes.[269]

These data raise the possibility that immature mesenchymal cells populate the synovium in RA, either as a primary event or as a repair mechanism. Similar primitive mesenchymal cells circulate in the peripheral blood of RA and normal persons, and in collagen-induced arthritis they infiltrate the synovium before synovial inflammation becomes clinically apparent.

Tissue repair in RA is a complex process that also involves the ingress or de-differentiation of mesenchymal cells that can remodel the matrix. These cells are modulated by TGF-β and the bone morphogenic proteins (BMPs). The BMPs are members of the TGF-β superfamily and, like TGF-β, they signal through the Smad pathway. Several members, including BMP-2 and BMP-7, are expressed in the joint and facilitate repair, although inappropriate release can also enhance joint damage or lead to ankylosis or enthesophyte formation.[270] BMP function is also regulated by a family of inhibitors such as Noggin, which can limit cartilage damage when it is overexpressed in murine antigen-induced arthritis. Modulating the relative balance and timing of BMP expression ultimately could be used to modify the destructive influence of synovitis or regenerate damaged tissues.

## CONCLUSION

The causes and pathogenesis of RA are complex and involve the interplay between environment and genes. Many years before clinical disease is apparent, evidence of immune dysregulation is observed, including antibody responses to modified peptides and increased production of cytokines and chemokines. Ultimately, a point is reached when antibodies activate complement in the joint and attract other immune cells from the blood. The local synovial milieu is rich with cytokines, inflammatory cells, and proteases that can drive further adaptive immune responses and joint damage. Understanding the diverse pathogenic events involved in RA helps us understand the diversity of responses to targeted agents that block TNF and IL-6, interfere with T cell co-stimulation, deplete B cells, or inhibit cytokine signal transduction. As we gain additional information about the critical events prior to clinical disease, that is, "pre-RA," approaches that prevent rather than treat RA might be feasible.

CHAPTER 70

# Clinical Features of Rheumatoid Arthritis

Alan R. Erickson • Amy C. Cannella • Ted R. Mikuls

**KEY POINTS**

- **Rheumatoid arthritis (RA) is a systemic inflammatory condition that typically appears as a polyarticular small joint arthritis of the hands and feet as well as extra-articular manifestations in some patients.**
- **Rheumatoid factor (RF) and anti-citrullinated protein antibody positivity is associated with pre-clinical RA, erosive and nodular articular disease, and systemic manifestations that include extra-articular involvement and reduced patient survival.**
- **Evidence suggests that pre-clinical and early RA might be triggered in extra-articular mucosal sites (oral and intestinal) in a genetically susceptible patient.**
- **Patients with RA usually are seen with a polyarticular inflammatory arthritis involving the small joints of the hands and feet, morning stiffness lasting longer than 1 hour, and laboratory findings indicative of systemic inflammation along with RF and anti-citrullinated protein antibody positivity.**
- **RA has a typical and several less common presentations, although all can develop typical radiographic findings, including periarticular osteopenia and marginal erosions.**

## EPIDEMIOLOGY AND DISEASE BURDEN

Rheumatoid arthritis (RA) is a systemic autoimmune condition with protean manifestations. The primary expression of disease occurs in the synovial tissues and is characterized by symmetric polyarticular inflammation, which can lead to progressive joint damage. As a result, RA is associated with substantial functional disability, morbidity, and accelerated mortality, which pose an enormous and growing societal burden.

### Disease Frequency

The prevalence of RA is estimated at 1% in most developed countries, with a frequency ranging from less than or equal to 0.1% to 1.9% in surveys from different parts of the world.[1] The highest rates of RA incidence are observed among individuals of Native American ancestry, with a reported disease prevalence approaching 5% to 7% in Pima and Chippewa Indians in the United States, respectively.[2,3] A much lower prevalence has been reported from select African regions and is thought to be the result of a lower population frequency of the human leukocyte antigen *(HLA)-DRB1* shared epitope-containing allele,[4] which is the single strongest known genetic risk factor for RA. A 40-year population-based study from Rochester, Minnesota (1955-1994) demonstrated an overall age- and sex-adjusted annual incidence of 44.6 cases per 100,000 person-years.[5] In this study, incidence rates were approximately twofold higher in women than men, with peaks in disease onset observed at younger ages in women (55 to 64 years) compared with men (75 to 84 years). Notably, these authors reported marked temporal trends, including a 47% decline in overall RA incidence during the study period. A follow-up investigation from the same study population, extending through 2007, suggested a more recent upsurge in disease incidence among women. These results underscore the potential impact of environmental exposures in mediating risk, and the potential relevance of birth cohort effects.[6] Based on this population, the lifetime risk for RA among U.S. adults has been estimated at 3.6% for women and 1.7% for men.[7]

### Disease Outcomes

Because of its systemic and polyarticular nature, RA can negatively impact physical functioning and health-related quality of life. Compared with individuals without arthritis, patients with RA in one study were 36% more likely to report fair or poor general health, twice as likely to report a health-related activity limitation, and almost 30% more likely to require assistance with personal care.[8] A second study of patients with RA with disease onset less than 1 year from enrollment found that 39% were unable to work after just 10 years of follow-up.[9] Rates of disability were highest among older patients, those with lower education, manual laborers, and those reporting more baseline physical impairment. Correspondingly, RA-related expenditures in the United States are staggering. In 2013 alone, health care costs were estimated to have exceeded $10 billion, and societal costs approached $45 billion.[10,11] The impact of RA on patient outcomes and health care spending is further amplified by its robust associations with comorbid conditions, including substantially higher rates of cardiovascular disease, serious infection, lymphoproliferative malignancy, and osteoporosis leading to fracture.[12]

In addition to detrimental effects on physical functioning and quality of life, RA portends an increased risk of mortality. In a pooled analysis of 18 cohort investigations conducted before 2001, Ward reported a mean standardized mortality ratio (SMR) of 1.70 across studies, with numerically lower mortality burdens seen in more contemporary publications and inception cohorts.[13] Factors associated

with reduced survival in RA have been identified and have included older age, poor functional status, comorbid conditions, extra-articular disease, autoantibody status (rheumatoid factor [RF] and anti-citrullinated protein antibody [ACPA]), disease activity, and medication use.[14-16] Although newer, highly effective biologic therapies have been available for more than a decade, the mortality gap in RA does not appear to have receded in recent years and may even be widening.[17] The excess mortality burden in RA appears to be largely driven by cardiovascular disease, a risk that may be partially mitigated by effective disease-modifying therapy, including methotrexate.[18] Additionally, with the recent emphasis on tighter treatment using effective disease measurement tools, it is expected we will realize a decrease in cardiovascular deaths with time.

## PRE-CLINICAL RHEUMATOID ARTHRITIS

Substantial recent gains have been made in our understanding of the risk factors and mechanisms involved in early disease development (see Chapter 69). It is now well established that circulating RF and ACPA (most often measured by using commercially available anticyclic citrullinated protein [anti-CCP] antibody assays) can be detected in approximately one-half of patients, often many years before RA symptom onset. The period of autoimmunity preceding the initial articular signs and symptoms of disease has been termed *pre-clinical* RA. In addition to detectable levels of serum autoantibody, pre-clinical RA is often characterized by the presence of subclinical inflammation that is reflected by increased serum levels of C-reactive protein (CRP) and other pro-inflammatory cytokines and chemokines. Several potentially relevant alterations in these serum biomarkers have been demonstrated that may herald imminent disease onset. Autoantibody changes include increased circulating concentrations and binding avidity, aberrant glycosylation (promoting complement activation and Fc receptor binding), and epitope spreading.

With the use of a multiplex antigen array and pre-clinical samples from the U.S. Department of Defense Serum Repository, investigators have demonstrated a time-dependent expansion of ACPA specificity, with an increasing number of positive ACPA subtypes, showing progression through the pre-clinical period and peaking at the time of RA symptom onset.[19] In this study, early ACPA expansion predicted subsequent increases in serum concentrations of inflammatory cytokines, including TNF, IL-6, IL-12p70, and interferon (IFN)-γ. Among patients in whom seropositive RA develops, the detection of these pre-clinical inflammatory cytokines and chemokines appears to predict a shorter time to disease onset. Furthermore, the concentration of these cytokines predicts disease onset in an age differential manner, and is longer in duration for older individuals (≥40 years) than younger individuals (<40 years).[20]

Mounting evidence suggests that early inflammatory events leading to RA may occur at extra-articular locations, with mucosal sites predominant among these.[21] Evidence supporting mucosal tissues as possible sites of initiation includes (1) the absence of demonstrable synovitis, either histologically or through the use of advanced imaging, in the vast majority of seropositive individuals during the pre-clinical period[22,23]; (2) the predominant role of environmental exposures that are known to cause mucosal injury as independent RA risk factors (e.g., cigarette smoking and, possibly, periodontitis)[24,25]; (3) the robust metrics of immunoglobulin (Ig)A-ACPA in predicting future disease onset[26]; and, perhaps most importantly, (4) evidence of demonstrable mucosal inflammation during the pre-clinical period. In a study of unaffected first-degree relatives (FDRs) of RA probands, individuals with high-risk autoantibody, defined by the presence of ACPA or two or more RF isotypes, were far more likely than seronegative FDRs to have detectable pulmonary airway abnormalities by high-resolution computed tomography (HRCT) (76% vs. 33%, $P = 0.005$),[27] an association that was independent of cigarette smoking. The prevalence and type of airway abnormalities observed in these high-risk FDRs were similar to those observed in patients with early-stage RA.

Other potential mucosal sites of initiation could include the oral or intestinal mucosa,[21] although evidence demonstrating inflammation from these sites in pre-clinical RA is lacking. Periodontitis is increased in frequency, even among patients with early, treatment-naïve RA compared with controls.[28] Moreover, infection with *Porphyromonas gingivalis* (the only prokaryotic organism with the ability to citrullinate protein antigen) has been associated with expression of disease-specific autoantibody in individuals at increased risk for RA.[29,30] In addition, recent work evaluating the intestinal microbiome has shown an abundance of *Prevotella copri* in patients with new-onset untreated RA compared with controls,[31] although mechanisms underpinning this association remain poorly understood.

In many patients, arthralgias herald the end of pre-clinical disease and often precede the onset of synovitis detected by physical examination. A recent study looked for the presence of synovitis by MRI in ACPA$^+$ arthralgia patients without clinical synovitis and compared them with asymptomatic controls. ACPA$^+$ arthralgia patients had more joint inflammation by MRI, differences that were most striking in the wrist joints ($P = 0.02$) with smaller differences observed in the small joints of the hands ($P = 0.06$) and feet ($P = 0.32$).[22] A robust correlation was observed between MRI-detected articular inflammation and measures of systemic inflammation, including CRP and erythrocyte sedimentation rate (ESR). During a 9-month follow-up period, RA developed in more than half (57%) of the ACPA$^+$ arthralgia patients according to the 2010 American College of Rheumatology/European League against Rheumatism (ACR/EULAR) classification criteria. Importantly, the magnitude of subclinical inflammation detected by MRI did not accurately predict those at risk for imminent RA; rather, the best predictors of progression included a greater number of joints involved and seropositivity for ACPA and/or RF.[22]

### Diagnosis

The characteristic patient with RA often reports pain and swelling of the small joints of the hands, wrists, and feet, with prolonged morning stiffness, often lasting more than an hour. This typical articular clinical presentation, along with laboratory and radiographic assessment, tools that are also used in classification criteria, are critical in differentiating RA from other inflammation-driven diseases. This is in

**TABLE 70-1** Factors Useful for Differentiating Early Rheumatoid Arthritis from Osteoarthritis

| | Rheumatoid Arthritis | Osteoarthritis |
|---|---|---|
| Age at onset | Across age spectrum, peak incidence in 50s | Increases with age |
| Predisposing factors | Susceptibility epitopes (HLA-DR4, HLA-DR1)<br>PTPN22, PADI4 polymorphisms, RF and ACPA positivity<br>Smoking | Trauma, overuse<br>Congenital abnormalities (e.g., shallow acetabulum) |
| Early symptoms | Morning stiffness and gelling phenomenon, pain improves with activity | Pain increases through the day and with use |
| Joints involved | Proximal interphalangeal joints, metacarpophalangeal joints, wrists most often; distal interphalangeal joints almost never | Distal interphalangeal joints (Heberden's nodes), Proximal interphalangeal joints (Bouchard's nodes), knees, lumbar spine |
| Physical findings | Soft tissue swelling, warmth | Bony osteophytes, minimal soft tissue swelling early |
| Radiologic findings | Periarticular osteopenia, marginal erosions, symmetric joint space narrowing in large joints | Subchondral sclerosis, osteophytes, asymmetric joint space loss in large joints |
| Laboratory findings | Increased C-reactive protein, positive RF, positive ACPA, anemia, thrombocytosis | Normal |

ACPA, Anti-citrullinated protein antibody; HLA, human leukocyte antigen; RF, rheumatoid factor.

comparison with osteoarthritis (OA), which is a far more prevalent "low-grade" inflammatory articular disease (Table 70-1). Early in the natural course, patients with RA may experience difficulty using their hands with routine activity, and pain in the forefeet with weight bearing or walking. Patients commonly report a "gelling" phenomenon following periods of rest, which improves with activity. Systemic symptoms such as fatigue and low-grade fever may also be present, but polyarthritis accompanied by a high fever (e.g., >38.5° C) suggests an alternative etiology. The joint examination often reveals swelling (or synovitis), tenderness, increased warmth, and limited range of motion. Other findings may include palmar erythema and subcutaneous nodules on extensor surfaces.

Adding to the complexity of early diagnosis, other rheumatic diseases included in the differential diagnosis of RA may share many of these findings. Diseases, which can be characterized by these typical joint findings, may also have a positive RF and include systemic lupus erythematosus (SLE), Sjögren's syndrome, and viral diseases, such as hepatitis B and C, and HIV (Table 70-2). Other diseases in the differential diagnosis include gout, particularly with tophi mimicking the subcutaneous nodules of RA, and calcium pyrophosphate dihydrate deposition (CPPD) arthropathy, with a pseudo-RA presentation. In elderly patients, polymyalgia rheumatica (PMR) and remitting seronegative symmetric synovitis with pitting edema (RS3PE) should be considered, whereas in younger patients, the signs and symptoms from parvovirus B19 infection or a postinfectious reactive arthritis can closely parallel those of RA. Conditions included in the differential diagnosis of RA and distinguishing characteristics are summarized in Table 70-2. The differential diagnosis will guide subsequent laboratory, serologic and radiographic assessments. In RA, the initial laboratory testing often shows the following results:

- Normal peripheral white blood cell (WBC) count and differential
- Thrombocytosis, reflecting increased systemic inflammation
- Mild normocytic anemia (anemia of chronic disease); less often microcytic
- Normal urinalysis
- Normal renal, hepatic, and other metabolic or endocrine testing
- Increased ESR (typically <50 mm/hr), and elevations CRP of similar magnitude. Both may be normal in as many as one-third of patients when first seen by a physician
- Normal serum uric acid
- RF seropositivity in approximately 70% at the time of diagnosis; an additional 15% of patients may "seroconvert" from $RF^-$ to $RF^+$ status early in the disease course
- ACPA seropositivity with a frequency approaching that observed with RF; in contrast to RF, ACPA positivity is highly specific (>95%)
- Negative anti-nuclear antibody (ANA), although as many as 30% of patients may be positive, typically in a low to moderate titer without positive subserologies
- Early in the disease process, radiographs are often normal, other than periarticular soft tissue swelling and evidence of effusions in some large joints

Arthrocentesis, if performed, typically demonstrates inflammatory synovial fluid with less than 50,000 WBC/$mm^3$ with the proportion of polymorphonuclear (PMN) cells typically less than 90%. Higher WBC and PMN counts in synovial fluid are more indicative of an infectious or crystalline etiology. Most often, synovial fluid values range between 5000 to 25,000 WBCs/$mm^3$ in RA, with 60% to 80% polymorphonuclear neutrophils (PMNs). Qualitative and nonspecific, the mucin clot test in RA classically demonstrates either no clot formation or an easily friable clot caused by a reduced concentration of synovial fluid hyaluronic acid in the context of inflammation. Both culture and crystal analyses are nearly universally negative in RA. Although lacking disease specificity, synovial fluid ragocytes (also called "rheumatoid cells" or "inclusion body cells") have been described in RA. Ragocytes are phagocytic cells with distinctive cytoplasmic granules that are thought to be composed of immune complexes. Other synovial fluid testing such as RF, ACPA, lactate, complement, and glucose are of little diagnostic utility in RA and thus are not indicated.

RA classification criteria have been developed for clinical trials and are based on components from the clinical

**TABLE 70-2** Rheumatoid Arthritis Differential Diagnosis and Discriminating Disease Features

| Disease | Distinguishing Features |
|---|---|
| **Other Connective Tissue/Idiopathic Forms of Arthritis** | |
| Adult-onset Still's disease* | Temperature >39° C for longer than 1 week, leukocytosis >10,000/mm$^3$ with >80% PMNs, evanescent rash, arthralgias, sore throat, lymphadenopathy, splenomegaly, liver dysfunction, marked elevations in serum ferritin |
| Systemic lupus erythematosus | Nonerosive arthritis with similar joint distribution and reducible deformities (Jaccoud's arthropathy), positive ANA with positive anti-dsDNA and other serologies, ACPA$^-$, associated internal organ involvement, especially the kidney |
| Spondyloarthropathy | Male predominance, often oligoarticular with predominantly large joint and lower extremity distribution, low back involvement, HLA-B27$^+$, RF/ACPA$^-$, uveitis, other associations, including psoriasis and inflammatory bowel disease |
| Vasculitis | Seronegative polyarthritis in a patient with systemic symptoms, such as fever, evidence of end-organ involvement; marked elevations in ESR or CRP; presence of anti-neutrophil cytoplasmic antibodies |
| Relapsing seronegative symmetric synovitis with pitting edema (RS3PE) | Marked by synovial thickening and joint tenderness with associated pitting edema of the hands, occurs in elderly men, very responsive to glucocorticoids, malignancy association; RF/ACPA$^-$ |
| Polymyalgia rheumatica | Arm and hip girdle involvement; marked elevations in ESR/CRP; RF/ACPA$^-$; association with giant cell arteritis |
| Sarcoidosis | Acute form associated with erythema nodosum and hilar adenopathy (Lofgren's syndrome), large joint involvement with a predilection for the ankle, often RF$^+$ and ACPA$^-$, nonerosive, pathology shows noncaseating granulomas |
| Sjögren's syndrome | Keratoconjunctivitis sicca (dry eyes) or xerostomia (dry mouth); salivary gland enlargement; positive ANA (SS-A/SS-B), often RF$^+$, ACPA$^-$ |
| Fibromyalgia | Myalgia without an inflammatory arthritis, RF and ACPA$^-$; ESR, CRP normal |
| **Infectious-Related** | |
| Bacterial endocarditis | High fever, predominantly large joints, audible murmur, positive blood cultures, evidence of peripheral emboli; can be RF$^+$, ACPA$^-$ |
| Human immunodeficiency virus | Brief acute joint pain associated with initial viremia followed by an oligoarticular process, fever |
| Hepatitis B and C | Nonerosive arthritis similar to RA, RF$^+$, ACPA$^-$, hypocomplementemia, positive HBV/HCV serologies, cryoglobulins |
| Parvovirus B19 | Nonerosive arthritis typically seronegative, self-limited process, parvovirus IgM$^+$, viral presentation |
| Chikungunya | Insect-borne virus, acute febrile illness with rash followed by a polyarthritis |
| Post-streptococcal infection | Nonerosive arthritis in a patient with an antecedent skin or oropharynx group A streptococcal infection, antistreptolysin O$^+$ |
| Rheumatic fever | Polyarthritis that is often additive, symmetric, with large joint lower extremity involvement; subcutaneous nodules, carditis, chorea, rash |
| Lyme disease | May have both an erosive and nonerosive arthritis, RF and ACPA$^-$, history of a tick bite and/or typical rash while in an endemic region |
| **Crystalline Arthropathy** | |
| Calcium pyrophosphate dihydrate deposition disease | Often in elderly women, 5% incidence of pseudo-RA presentation, radiographs may have chondrocalcinosis; associations with hemochromatosis, hyperparathyroidism, hypothyroidism, and hypomagnesemia |
| Polyarticular gout | Often involves distal joints, including first MTP, and may affect the DIP joints of the hands, associated tophaceous nodules, RF/ACPA$^-$, erosions with "overhanging edge"; hyperuricemia |
| **Systemic Manifestations of Other Medical Conditions** | |
| Thyroid disease | Polyarthralgias and myalgias with other manifestations of thyroid disease; carpal tunnel symptoms may be present |
| Malignancy | Often represents a paraneoplastic process and can mimic RA; lymphoma can present like RA; may be RF$^+$ but usually ACPA$^-$ |
| Hypertrophic osteoarthropathy | Predominant involvement in knees, ankles, wrists; associations with chronic lung disease (e.g., cystic fibrosis) and malignancy; bone pain and periostitis |

*See criteria of Yamaguchi M, Ohta A, Tsunematsu T, et al: *J Rheumatol* 19:424–430, 1992.

ACPA, Anti-citrullinated protein antibodies; ANA, anti-nuclear antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; DIP, distal interphalangeal; HLA, human leukocyte antigen; MTP, metatarsophalangeal; RF, rheumatoid factor.

**TABLE 70.3** 1987 American College of Rheumatology (Formerly American Rheumatism Association) Criteria for Classification of Rheumatoid Arthritis*

| Criterion | Definition |
|---|---|
| Morning stiffness | Morning stiffness in and around the joints lasting at least 1 hour before maximal improvement |
| Arthritis of ≥3 joint areas | At least 3 joint areas simultaneously having soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician (the 14 possible joint areas are [right or left] PIP, MCP, wrist, elbow, knee, ankle, and MTP joints) |
| Arthritis of hand joints | At least one joint area swollen as described previously in wrist, MCP, or PIP joint |
| Symmetric arthritis | Simultaneous involvement of the same joint areas (as in criterion 2) on both sides of the body (bilateral involvement of PIP, MCP, or MTP joints is acceptable without absolute symmetry) |
| Rheumatoid nodules | Subcutaneous nodules over bony prominences or extensor surfaces, or in juxta-articular regions, as observed by a physician |
| Serum rheumatoid factor | Demonstration of abnormal amounts of serum rheumatoid factor by any method that has been positive |
| Radiographic changes | Changes typical of RA on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized to or most marked adjacent to involved joints (OA changes alone do not qualify) |

*For classification purposes, a patient is said to have RA with presence of four of the seven criteria: criteria 1 through 4 must be present for ≥6 weeks.

MCP, Metacarpophalangeal; MTP, metatarsophalangeal; OA, osteoarthritis; PIP, proximal interphalangeal; RA, rheumatoid arthritis.

history, physical examination, and laboratory and radiographic testing. Satisfaction of the 1987 ACR RA classification criteria requires the presence of objective synovitis for 6 weeks or longer to exclude alternative self-limited forms of arthritis.[32] Other components of these criteria are shown in Table 70-3. Because these criteria include findings more consistent with long-standing disease, such as the presence of radiographic damage and subcutaneous nodules, the 1987 criteria lack sensitivity for the detection of early RA. Recognizing the importance of both early diagnosis and treatment, new RA classification criteria were proposed as part of a joint ACR/EULAR effort in 2010 (Table 70-4).[33] The new criteria place an emphasis on additional serologic tests, including RF as well as ACPA, ESR, and CRP. Articular involvement is qualified by joint swelling and tenderness. Application of these criteria provides a score of 0 to 10, with a score of 6 being indicative of the presence of definite RA. The 2010 criteria render an earlier diagnosis possible, even with a very low (or in some cases absent) number of tender and/or swollen joints. Although the 2010 criteria yield excellent sensitivity (97%) in identifying patients with RA, the specificity is substantially lower than that of the 1987 criteria (55% vs. 76%, respectively).[34] By default, satisfaction of the 1987 criteria satisfies the 2010 criteria, the latter including provisions for the use other imaging modalities (e.g., ultrasound or MRI) to document the presence of synovitis. Although useful for teaching and

*Joint involvement refers to any swollen or tender joint on examination, or evidence of synovitis on magnetic resonance imaging or ultrasonography. Distal interphalangeal joints, first carpometacarpal joint, and first metatarsophalangeal joint are excluded from assessment. Categories of joint distribution are classified according to the locations and numbers of involved joints, with placement into the highest category possible based on the pattern of joint involvement.

†Medium to large joints refer to shoulders, elbows, hips, knees, and ankles.

‡Small joints refer to the metacarpophalangeal joints, proximal interphalangeal joints, metatarsophalangeal joints 2 through 5, thumb interphalangeal joints, and wrists.

§In this category, at least one of the involved joints must be a small joint; the other joints can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular).

‖Individuals should be scored by these criteria only if at least one serologic test and at least one acute phase reactant test result are available. If a value for a serologic test of acute phase reactant is not available, that test should be considered as negative/normal.

¶Negative refers to international unit (IU) values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to IU values that are greater than the ULN but less than or equal to 3 × ULN for the laboratory and assay; high-positive refers to IU values that are greater than 3 × ULN for the laboratory and assay. Where RF is available only as positive or negative, a positive result should be scored as low-positive for RF.

#Normal/abnormal is determined by local laboratory standards.

**Duration of symptoms refers to patient self-report of the duration or signs or symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment.

ACPA, Anti-citrullinated protein antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor; ULN, upper limit of normal.

Modified with permission from Aletaha D, Neogi T, Silman AJ, et al: 2010 rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative, *Ann Rheum Dis* 69:1580–1588, 2010.

in clinical practice, it is important to recognize that both the 1987 and 2010 criteria were primarily developed with the goal of identifying homogeneous study populations for RA clinical trials and not for the diagnosis of individual patients.

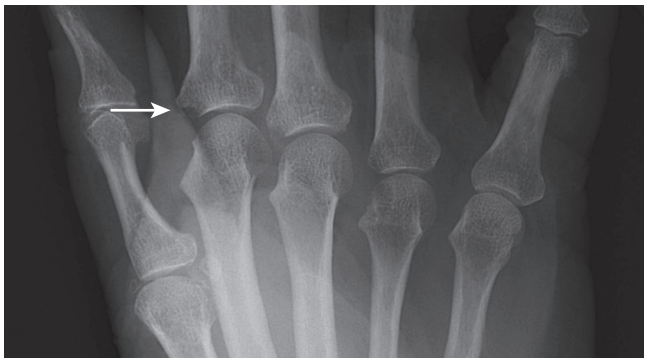

**Figure 70-1** Typical rheumatoid arthritis erosion *(arrow)* along the periarticular area where the synovium wraps-back on itself, the so-called "bare area." *(Courtesy Dr. Gerald Moore.)*

Radiographic assessments are an important element in the RA evaluation, serving as a robust measure of treatment efficacy in therapeutic trials. Although radiographic assessments used in clinical trials focus primarily on quantitative measures of articular damage, including bony erosions and joint space narrowing which is limited to the hands, wrists and feet, it is well recognized that RA affects a number of other joints, with findings that can be highly characteristic and markedly destructive. Often accompanied by periarticular osteopenia, bony erosions in RA are distinctive in location, affecting the so-called "bare area" where synovium wraps back on itself and lays directly on the bone. This bare area is located periarticularly in the proximal and distal metaphyseal regions (Figure 70-1). Other imaging modalities may assist in diagnosis. Both ultrasound and MRI appear to have superior sensitivity over conventional radiography for the detection of bony erosions in RA (see Chapter 58) and for the identification of synovitis when results from physical examination are equivocal. Bony ankyloses, confirmed radiographically, is rare in RA and is associated with increased duration and severity of disease, and is found in joints that have been immobilized by pain, inflammation, treatment, or any of these factors in combination.

## CLINICAL PRESENTATIONS OF EARLY RHEUMATOID ARTHRITIS

The early presentation of RA includes mild systemic and articular signs and symptoms. Extra-articular features are more commonly seen in later disease. The systemic findings include fatigue and, less commonly, weight loss or low-grade fever. Articular symptoms most often begin with stiffness, pain, and swelling involving the small joints of the hands and feet in a symmetric distribution, including the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and metatarsophalangeal (MTP) joints. Understanding that RA-related synovitis can involve almost any synovial joint in the body, the condition characteristically spares the distal interphalangeal (DIP) joints (impacting <10% of cases)[35] and also spares the thoracic and lumbosacral spine. Joint activity in RA rarely remits completely in an involved joint, while developing in another. This additive quality of arthritis distinguishes RA from conditions such as rheumatic fever, serum sickness, or palindromic rheumatism, which can be characterized by a true migratory arthritis pattern. Among patients with an early undifferentiated inflammatory arthritis, 30% to 40% will experience a spontaneous remission, whereas classifiable RA will eventually develop in approximately 1 in 4. In addition to ACPA positivity, other features predictive of RA development in patients with early undifferentiated inflammatory arthritis include polyarthritis, symmetric arthritis, and the presence of radiographic erosions.[36]

### Patterns of Onset

RA onset typically follows one of several different temporal patterns, ranging from an acute or "explosive" polyarticular disease onset to a far more insidious inflammatory arthritis that can be oligoarticular and additive during the initial course.

#### Insidious Onset

Estimated to impact 55% to 65% of patients,[37] an insidious disease onset represents the most common early presentation of RA. The small joints of the hands, wrists, and feet are most commonly affected.[38] The joint pattern is often symmetric, and is accompanied by morning stiffness, a cardinal sign of inflammatory arthritis that may last as long as several hours. Less commonly, onset is characterized by a slowly evolving monoarticular or oligoarticular presentation, with a predilection for larger joints, such as the elbows, knees, or hips. This presentation mimics a seronegative spondyloarthropathy, but with time, most patients experience symptoms in additional joint areas, including the contralateral joint or other small joints, resulting in a pattern of involvement more typical of RA. In older patients (e.g., >65 years), an insidious onset can be dominated by systemic features, including fever, weight loss, fatigue, marked acute phase responses, and occasional proximal girdle involvement, which together parallel the signs and symptoms of PMR or RS3PE. This type of presentation should also prompt consideration of an occult malignancy.[39]

#### Acute or Intermediate Onset

Estimated to impact 8% to 15% of all cases, RA less frequently manifests as an explosive polyarticular arthritis that can be intensely inflammatory and may involve both small and large joints when the patient is first seen by a physician. With acute onset, the pain may be so limiting that the initial evaluation occurs in an urgent ambulatory setting. This dramatic, but uncommon, disease onset appears to have a predilection for the elderly and has been described as one of the characteristic presentations in "elderly-onset" or "later-onset" RA. An intermediate disease onset, in which symptoms develop over days to weeks, impacts approximately 1 in 5 incident cases.

#### Atypical Onset

In a minority of patients with RA, the initial presentation involves a simple bursitis or tendonitis that may evolve into tenosynovitis. Such patients may also be seen with early carpal tunnel syndrome from wrist involvement and subsequent median nerve compression. As with insidious

presentations, the disease in individuals with an atypical presentation often evolves during time to the more typical symmetric small joint findings of RA.

### Other Patterns of Onset

**Palindromic Rheumatism.** Palindromic rheumatism is an uncommon form of disease onset characterized by relatively brief but intense episodes of joint inflammation. Often, by the time a patient is seen by a rheumatologist, they may already be asymptomatic, because of the self-limited nature of palindromic flares, which may last from a few hours to a few days.[40] Joint involvement with palindromic onset is often monoarticular, with maximal inflammation achieved within just hours. Impacting almost any joint, this onset most commonly affects the patient's knees, fingers, or shoulders. Because of the highly inflammatory, and often monoarticular presentation, palindromic RA can closely mimic crystalline arthropathy or septic arthritis. Serologic testing, including RF and/or ACPA, is often helpful in confirming the diagnosis of palindromic rheumatism.[41] If followed over time, one-third to one-half of patients with initial palindromic rheumatism evolve to develop a daily pattern of joint involvement more typical of RA.[40] This disease evolution appears to be more common among those with hand involvement and ACPA positivity.[41] The disease in the remainder of patients tends to continue to palindrome or evolve into a definable crystal-related arthropathy.

**Arthritis Robustus.** As with palindromic onset, arthritis robustus is a relatively uncommon RA subtype that was first described by de Haas et al in 1973.[42] The typical patient profile is an older man, with an occupational history notable for manual labor. Patients seen with arthritis robustus often have a markedly inflammatory arthritis, usually involving the hands and feet. However, affected patients often have few if any symptoms, giving the impression in some cases of a patient who is "blissfully unaware" of the condition.[43] The challenge in the care of these patients is they often do not communicate complaints, which makes the physical examination and laboratory assessments the key components in physician management decisions.[43]

**Extra-articular Disease as Initial Presentation.** Several reports have shown that extra-articular disease manifestations rarely represent the initial disease manifestation in RA. This relatively uncommon phenomenon has perhaps been most widely observed with the appearance of rheumatoid nodules preceding demonstrable synovitis.[44] "Rheumatoid nodulosis" has been classically described by the combination of rheumatoid nodules, subchondral bone cysts, and recurrent joint symptoms, an entity with a favorable prognosis most often seen in the context of RF seropositivity.[45] More rarely, other forms of extra-articular disease have been observed to precede the development of synovitis in patients with RA, most notably lung disease.[46] Fischer and colleagues examined 74 patients who were seen with respiratory symptoms and a positive ACPA but without evidence of RA or alternative connective tissue disease.[46] Investigators noted four distinct radiographic patterns using thoracic HRCT, including isolated airways disease (54%), isolated interstitial lung disease (ILD) (14%), mixed airways disease and ILD (26%), and combined pulmonary fibrosis and emphysema (7%). Among the 33 patients with high-titer ACPA, articular symptoms of RA developed in 3 during a median follow-up of approximately 1.2 years.

## COURSE AND COMPLICATIONS OF ESTABLISHED RHEUMATOID ARTHRITIS

### Articular Manifestations

With its primary manifestation involving synovial tissues, the signs and symptoms of RA are primarily driven by active synovitis that results in joint swelling, stiffness, palpable warmth, and pain. The classic joint distribution in early disease includes the small joints of the hands and feet (MCP, PIP, and MTPs) (Figure 70-2A). With time, intermediate (wrists, elbows, and ankles) and large (hips, shoulders, and cervical spine) joints may become involved. With more advanced and longer duration of disease, RA may also involve atypical joints, including the temporomandibular joint (TMJ), cricoarytenoid, and sternoclavicular joint. In contrast to OA, RA rarely affects the DIP joints and seldom targets the thoracic or lumbosacral spine.

### Hands and Wrists

The hands and wrists are often considered together because they form a single functional unit. For example, wrist involvement is strongly associated with the presence of ulnar deviation of the MCP joints.[47] This may occur via weakening of the extensor carpi ulnaris muscle or tendon, either as a direct or indirect result of inflammation, which leads to radial deviation of the wrist as the carpal bones rotate (the proximal row in an ulnar direction and the distal row in a radial direction). Subsequently, ulnar deviation of the MCP joints, and associated palmar subluxation, may serve as compensatory mechanisms to maintain digital tendons in a normal line with the radius. Together, changes of the wrist and MCP joints result in a highly characteristic "zigzag" deformity (Figure 70-2B and C). Although classically described as irreversible, reducible ulnar deviation of the MCP joints can result from bulky synovitis, tendon laxity occurring after the reduction of synovitis, tendon rupture, or muscle weakness in the hands. However, reversible MCP deviation is more typical of nonerosive processes such as SLE or non-inflammatory neurologic conditions such as Parkinson's disease.

Proliferative synovium contains both the inflammatory and enzymatic machinery sufficient to destroy ligaments, tendons, and the articular regions distal to the ulnar head, resulting in joint subluxation, dislocation, and bony erosions. This inflammatory synovium may also invade and impinge normal tissue spaces, and lead to nerve entrapments syndromes, such as carpal tunnel syndrome (median nerve). The inflammatory and enzymatic degradation of tissue, coupled with naturally occurring forces, act together to impair the integrity of the radiocarpal, radioulnar, and midcarpal joints. The ulnar collateral ligament can become stretched or even destroyed by synovitis of the radioulnar joint. As a result, the ulnar head may "spring up" into dorsal prominence where it "floats" and can be easily depressed (the so-called "piano key styloid") (Figure 70-3). Severe disease progression in the wrist can lead to marked loss of

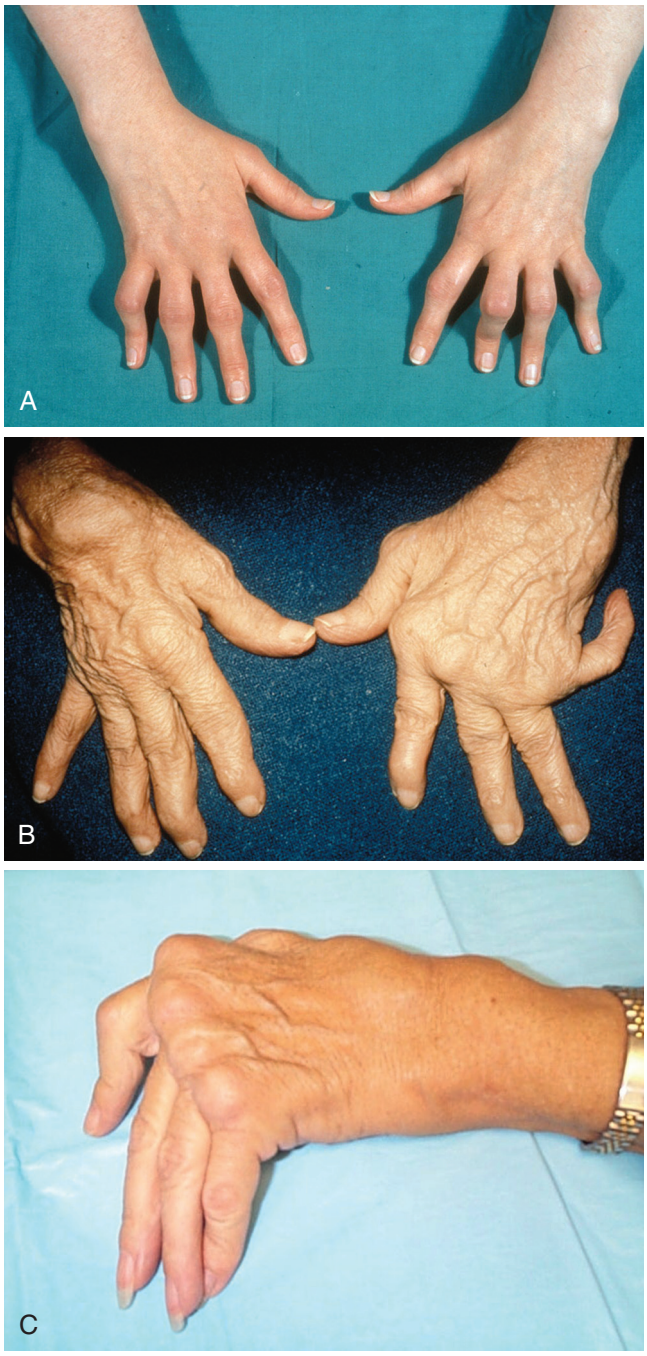

**Figure 70-2** **A,** Polyarticular arthritis with fusiform swelling of the proximal interphalangeal joints along with wrist deformity. **B,** Complete subluxation with ulnar deviation at the metacarpophalangeal joints in a patient with advanced disease. **C,** "Zig-zag" deformity of the hand. joint space, bone erosions, and ankyloses; the latter is more common with wrist immobilization resulting from unremitting disease.

Perhaps the best recognized of the articular deformities observed in RA are swan neck and boutonnière deformities of the fingers (Figure 70-4Aand B). The swan neck deformity involves DIP flexion with simultaneous PIP hyperextension. This condition is thought to result from direct

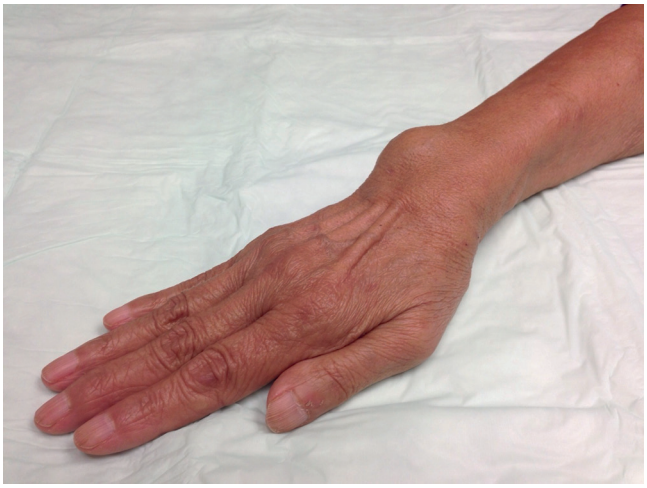

**Figure 70-3** "Piano key styloid." Rheumatoid arthritis wrist involvement that leads to damage of the ulnar collateral ligament with resultant prominence, or floating, of the ulnar head and styloid. *(Courtesy Dr. Amy Cannella.)*

involvement of the PIP and/or MCP joints. Boutonnière deformities result from PIP flexion and DIP hyperextension and are related to relaxation of the central slip, with buttonholing of the PIP joint between its lateral bands. Involvement of the thumb in RA also has unique characteristics. Several corresponding deformities are described, and result from involvement of the first MCP, interphalangeal (IP) or carpal metacarpal (CMC) joints, either alone or in combination. Predominant thumb deformities include a boutonnière-like deformity, which begins with synovitis of the first MCP joint, results in weakening of the joint capsule and surrounding connective tissues, and culminates with the subluxation of the extensor pollices longus (EPL) tendon in both volar and ulnar directions. As a result, the MCP joint is abnormally flexed and the IP joint is secondarily hyperextended, forming a characteristic "Z-deformity" (see Figure 70-4C). The MCP joint may be partially reducible or fixed. Less commonly, RA patients develop a swan neck–like deformity of the thumb, resulting from CMC synovitis and joint subluxation at the base of the thumb. This ultimately leads to exaggerated adduction at the distal end of the MCP joint, markedly narrowing the first web space and effectively reducing the object size that a patient can grasp. In a recent survey of 100 patients with established RA, almost half (47%) had evidence of hand or wrist deformity on examination. Longer disease duration was the only factor found to be associated with these findings.[48] Among patients with deformity, the most common findings included radial deviation of the wrist (91%), ulnar drift of the MCPs (79%), Z-deformity of the thumb (56%), swan neck deformity (49%), boutonnière deformity (43%), palmar subluxation of the MCPs (36%), and wrist subluxation (28%).

One of the most common manifestations of RA in the hands is tenosynovitis in flexor tendon sheaths, which can be a major cause of hand weakness.[49] Along with wrist joint synovitis, flexor tenosynovitis occurs in close proximity to the median nerve, and may result in carpal tunnel syndrome through impingement, similar to synovitis of the carpal joints. Tenosynovitis may occur in as many as one-half of patients with RA, and manifests as diffuse volar swelling of the phalanges or as a palpable grating of the flexor tendon

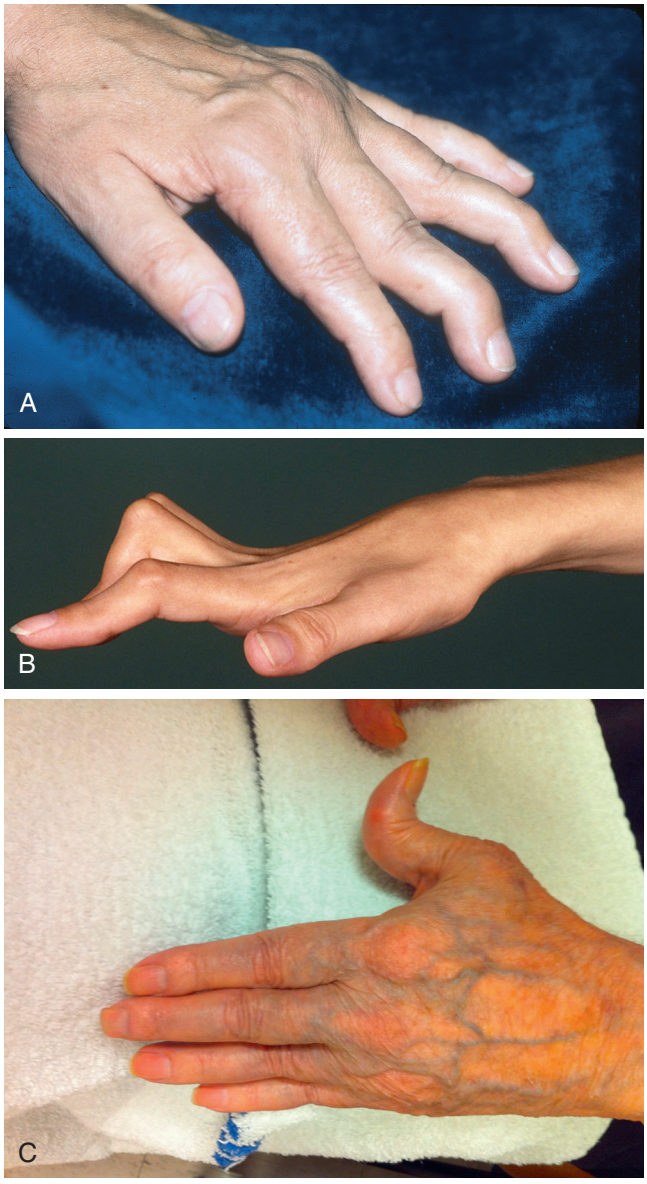

**Figure 70-4** **A,** Swan neck deformity. This deformity is marked by hyperextension of the proximal interphalangeal joint and flexion of the distal interphalangeal joints. **B,** Boutonnière deformity. This deformity is marked by flexion of the proximal interphalangeal joint and extension of the distal interphalangeal joint. **C,** "Z-deformity" of the thumb. *(**A** and **B**, Courtesy Dr. Iain McInnes; **C**, Courtesy Dr. Amy Cannella.)*

sheaths in the palm. Without concomitant and typical RA synovitis, this finding may pose a substantial diagnostic challenge. Nodular thickening may also develop in the tendon sheaths or the pulley system and cause the finger to "lock" in fixed flexion ("trigger finger"), resulting in significant pain. With chronic symptoms or frequent recurrence, trigger finger can be treated with tendon sheath injection or surgical intervention.

RA also represents the most common etiology of tendon ruptures involving the hand. Described by Vaughn-Jackson in 1958, RA can lead to attritional rupture of the digital extensor tendons, occurring at the ulnar head in the wrist.[50] Because surgical intervention can prevent extensor tendon rupture and subsequent loss of function, identifying patients most at risk for this complication is paramount. In extensor

**Figure 70-5** Tendon rupture of the fourth and fifth digits of the hand. Note the significant wrist swelling and prominence of the ulnar styloid region. This condition requires immediate orthopedic evaluation.

tendon rupture, the extensor digiti minimi (EDM) usually ruptures first, a defect that may go unnoticed because the extensor digitorum communis (EDC) extends all four fingers simultaneously. Thus, testing for EDM function, via active independent extension of the little finger, may be valuable in identifying patients that could benefit from prophylactic extensor tendon repair[51] (Figure 70-5). Less frequently, RA may lead to rupture of the extensor pollices longus in addition to attritional ruptures of the flexor pollices longus and the index finger flexor digitorum profundus tendons within the carpal tunnel.[52]

Although more typical of severe psoriatic arthritis, the most serious consequence of RA involving the hand can be seen with marked bone resorption that begins with the articular cartilage and spreads along the diaphysis of involved phalanges. As a result, the digits can become grossly shortened, exposing excess skin folds, and the phalanges can be retracted (or telescoped) into one another and then pulled out into abnormally long extension often without eliciting pain. Typically involving multiple digits, this rare arthropathy has been termed "arthritis mutilans" or the "opera glass hand."

## Feet and Ankles

As with the hand and wrist, the foot and ankle may also be considered as a single functional unit. For example, hindfoot abnormalities that involve the ankle and/or subtalar joint have been shown to directly impact forefoot pressures with loading and weight bearing; results that suggest optimal correction of an existing forefoot deformity is reliant upon simultaneous correction of any residual hindfoot defect. Ankle and foot involvement is common in RA, with forefoot involvement (primarily MTP synovitis) observed in as many as 90% of patients at some point in the disease process, and serving as the initial disease manifestation in approximately 15% of patients.

As a result of forefoot/MTP involvement, pain experienced during push-off in striding results in altered gait mechanics. Plantar subluxation of the metatarsal heads occurs soon after the MTP joints become involved, producing "cock-up" or "claw" toe deformities of the PIP joints. Cystic collections that represent outpouchings of flexor

tendon sheaths often develop under the MTP joints.[53] Pressure necrosis and calluses of the plantar surfaces can develop in patients with subluxation of metatarsal heads, and claw deformities can lead to pressure ulcers on the dorsal surface of PIP joints (Figure 70-6). Metatarsal subluxation leads to increased pressure on the MTP joints, with a sensation described by many patients as "walking on marbles." Concurrently, hallux valgus results in progressive overlap of the second and third toes on top of the great toe. With the development of fixed deformities, including a broadened forefoot, hallux valgus, and claw toes, mechanical foot symptoms often persist in patients, even in the absence of active inflammation.

Involvement of the hindfoot, midfoot, and adjacent joints are also common in RA. Valgus deformity of the hindfoot may occur, likely related to pronation forces applied to weakened and inflamed talonavicular and subtalar joints (Figure 70-7). Similarly, ankle instability may result from stretching and even erosion of ligamentous support tissues. With involvement of the subtalar joint, which provides the major axis for foot inversion and eversion, patients may report difficulty with ambulation on uneven ground. With midfoot involvement, inflammation of the talonavicular and naviculocuneiform joints can result in pes planus (flat foot) deformities. Pes planus can be further exacerbated through insufficiency of the posterior tibialis tendon and the plantar calcaneonavicular (spring) ligament, and result in collapse of the longitudinal arch. Inflammation and subluxation of the tarsometatarsal joints may result in "rocker-bottom" foot deformity, resembling that observed with Charcot's foot disease. Rheumatoid nodules can develop in the Achilles tendon, and spontaneous tendon rupture has been reported to occur in the context of granulomatous inflammation.[54] Parallel to carpal tunnel syndrome in the wrist, tarsal tunnel syndrome can occur in the ankle and results in a compressive tibial neuralgia.

**Figure 70-6** Pressure ulcers are most likely to occur at areas of deformity on or over the plantar region of the metatarsal phalangeal joints. ## Cervical Spine

Cervical spine involvement may be seen in as many as 80% of patients with RA and appears to be most common in those with long-standing and poorly controlled disease. Reviewed by Joaquim and Appenzeller,[55] risk factors for cervical spine involvement in RA include erosive disease, glucocorticoid use, treatment failure, and early age at disease onset. Importantly, the development of cervical spine involvement and its complications may be abrogated by intensive treatment. One study showed that patients treated aggressively with combination disease-modifying therapy were at lower risk for cervical spine disease than patients treated with less aggressive monotherapy.[56]

Of the cervical spine findings observed in RA, the most serious clinical presentations relate to atlantoaxial (C1-C2) subluxation, cranial settling, and subaxial subluxation. Of these, atlantoaxial subluxation is the most common radiologic abnormality of the cervical spine observed[55] and may include:

- The atlas (C1) moving anteriorly on the axis (C2) (most common)
- The atlas moving posteriorly on the axis
- Subluxation of the atlas vertically in relation to the axis (least common)

The earliest and most common symptom of atlantoaxial subluxation is pain radiating into the occiput. Two other serious, but less common, clinical patterns include (1) slowly progressive spastic quadriparesis with painless sensory loss in the hands, and (2) transient episodes of medullary dysfunction associated with vertical penetration of the dens and probable vertebral artery compression. In the latter case, paresthesias may occur in the shoulders or arms during movement of the head. With vertical C1-C2 subluxation, patients may complain of facial pain with decreased sensation in the V1 and V2 distributions of the fifth cranial nerve.

Neurologic symptoms resulting from spinal cord involvement often have little relationship to the degree of C1-C2 subluxation present. When present, symptoms range from simple paresthesias to altered consciousness, loss of sphincter tone, and other well-defined signs of cord compression. Signs of cord compression portend a poor prognosis, often heralding the rapid progression of myelopathy with an approximate 50% 1-year mortality.[57] Risks are further

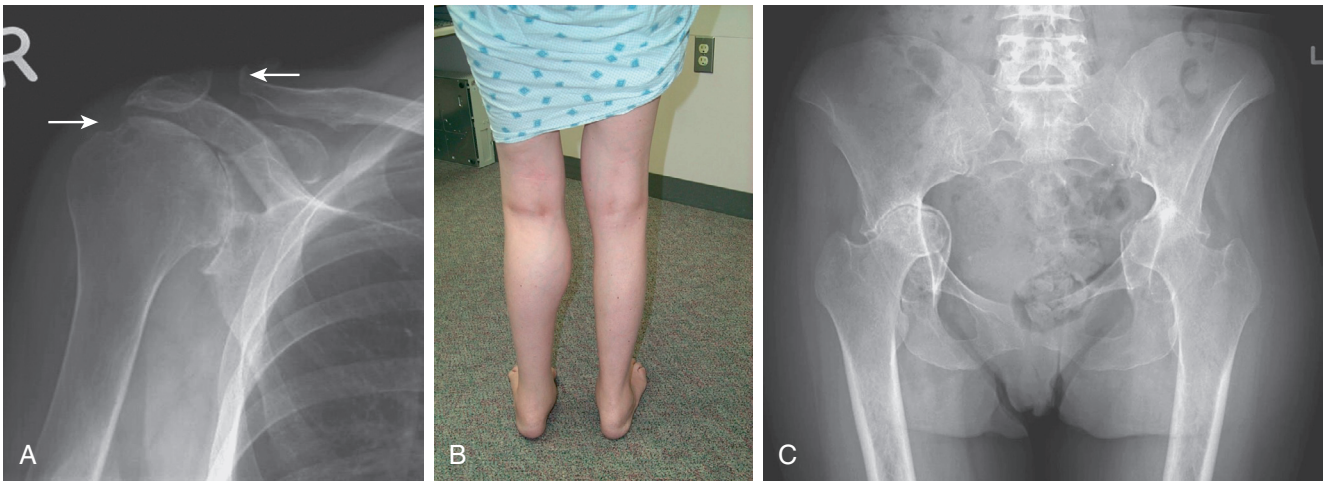

**Figure 70-8** **A**, Shoulder findings in rheumatoid arthritis include glenohumeral joint space narrowing with marginal erosions and cystic changes of the humeral head *(lower arrow)*, a high-riding humeral head indicative of a rotator cuff tear, and tapering of the distal end of the clavicle with widening of the acromioclavicular joint *(upper arrow)*. **B**, Ruptured Baker's cyst of the left calf with an associated pseudothrombophlebitis. **C**, Bilateral protrusio acetabuli. magnified in the context of patient falls, whiplash injury, or the need for general anesthesia with intubation requiring cervical manipulation. The incidence of sustained neurologic deterioration following surgical correction of C1-C2 disease may be as high as 6%, suggesting that a conservative management strategy may be optimal for a substantial proportion of asymptomatic patients.

As with neurologic symptoms, physical examination findings are nonspecific and unreliable in detecting C1-C2 subluxation. Physical findings may include the loss of cervical lordosis, resistance to passive spine motion, or the abnormal protrusion of the axial arch felt with the examining finger on the posterior pharyngeal wall. In symptomatic patients, cervical spine films in flexion should be taken only after radiographs have been taken to rule out odontoid fracture or high-grade atlantoaxial subluxation. Advanced imaging modalities, including CT and especially MRI, have proven to be particularly useful in defining pathology affecting this region in RA (see Chapter 58).

Although not lined by synovium, discovertebral joints of the cervical spine can be involved, leading to osteochondral tissue destruction and disk space narrowing that is visible on lateral radiographs. Patients with cervical spine involvement may report significant neck pain, although passive range of motion may be preserved in the absence of significant muscle spasm. At least two possible mechanisms have been proposed to explain the cervical spine involvement characteristic of RA: (1) extension of inflammation from adjacent synovial-lined neurocentral joints (the joints of Luschka) into the discovertebral area, and (2) chronic cervical instability initiated by apophyseal joint destruction, leading to vertebral misalignment or frank subluxation.

### Intermediate and Large Peripheral Joints

Intermediate and large joint involvement is more indicative of long-standing and often poorly controlled disease. Elbow involvement is reported in approximately one-third to one-half of patients. The earliest clinical manifestation is extension loss, a finding that frequently goes unnoticed by the patient. Bilateral olecranon bursal swelling is observed in RA, and may be encountered in gout or pseudogout, although typically unilaterally. Shoulder involvement impacts not only the glenohumeral joint, but also the subacromial (subdeltoid) bursa, the distal third of the clavicle (related to adjacent inflammatory bursitis), and rotator cuff tendons (Figure 70-8A). In contrast to other joints, shoulder involvement is often quite painful, with symptoms referred to the deltoid region. Patients commonly complain of significantly disturbed sleep with painful awakenings in side sleeping positions. Rotator cuff dysfunction is common in RA, and may relate to the proximity of proliferative synovium to the rotator cuff insertion on the greater tuberosity. Resulting in substantial morbidity, rotator cuff tears have been demonstrated to impact approximately 20% of patients with RA, with another one-fourth having evidence of frayed tendons.[58] Because the rotator cuff acts as a downward stabilizer of the humerus in the glenoid, rotator cuff dysfunction can lead to superior migration of the humeral head from unopposed forces of the deltoid, and resultant secondary degenerative arthritis of the glenohumeral joint.

Hip and knee involvement also results in substantial disability. In contrast to the hip, knee involvement in RA is usually readily identified on examination, with joint effusions that can be large and associated with increases in intra-articular pressures. As with the elbow, loss of full extension may be an early finding of knee involvement. Increased intra-articular pressure, particularly those accompanying flexion, can lead to an outpouching of the posterior components of the joint, resulting in a popliteal or Baker's cyst. In extreme circumstances, a Baker's cyst can rupture, and inflammatory fluid may dissect distally into the calf, resembling acute thrombophlebitis or deep vein thrombosis (see Figure 70-8B). A helpful but uncommon sign of cyst rupture is the presence of a crescentic hematoma inferior to either the lateral or medial malleolus. MRI and ultrasound are often used to identify a Baker's cyst and help to differentiate this complication from other entities.

Unlike the knee, detecting involvement of the hip often poses a challenge. As with other forms of arthritis, including

OA, hip involvement in RA is associated with pain most often localized to the groin or occasionally the buttock. Similar to other forms of inflammatory arthritis involving the hip, RA leads to symmetric joint space narrowing. Symmetric cartilage loss in RA leads to an axial migration of the femoral head. This is in contrast to OA of the hip, which is characterized by asymmetric joint space narrowing that is most evident in the superior aspect of the joint. In advanced cases of RA-related hip involvement, the femoral head can collapse and undergo resorption with remodeling and medial migration of the acetabulum, leading to protrusio acetabuli (see Figure 70-8C). Well recognized in RA, protrusio acetabuli may also be seen in other forms of inflammatory arthritis, including spondyloarthropathies, and has been described in non-inflammatory connective tissue disorders such as Stickler's syndrome.[59]

### Temporomandibular, Cricoarytenoid, Sternoclavicular and Manubriosternal Joints

Though not commonly thought of as synovial joints, both the TMJ and cricoarytenoid joint contain synovial tissue and can be affected in RA. Patients with TMJ involvement often complain of jaw pain, which can be confused with tooth or ear problems or jaw claudication in the elderly, in whom giant cell arteritis with polymyalgia rheumatic may be suspected. As in other joints, radiographic findings of the TMJ in RA can include both joint space narrowing and erosions. Symptoms of cricoarytenoid joint involvement are often far subtler. The cricoarytenoid joints are diarthrodial joints responsible for rotation of the vocal cords as they abduct and adduct. With cricoarytenoid joint involvement in RA, a patient may complain of new-onset hoarseness, sore throat, dysphagia, or pain with speech. In extreme cases, the vocal cords can become immobilized in an adducted midline position, resulting in inspiratory stridor. Laryngoscopy and CT scanning are the most sensitive methods to evaluate for cricoarytenoid arthritis. Finally, as synovial lined joints, both the sternoclavicular and manubriosternal joints can also be involved in RA, although this rarely causes symptoms due to their relative immobility. Overt involvement of the sternoclavicular joint should raise suspicion for possible septic arthritis.

## Extra-articular Manifestations

Recognizing that RA is a systemic inflammatory disease is a key requisite for optimal management. Inflammation in RA involves not only articular structures but may also involve extra-articular tissues, leading to the development of subcutaneous nodules and other mucocutaneous findings, serositis, cardiopulmonary, neurologic, ocular, and hematological complications, to name just a few. The most significant extra-articular features are related to vascular inflammation and vascular damage. Extra-articular manifestations are observed in up to 50% of patients with RA and generally portend a poor prognosis, including increased morbidity and mortality.[7] In a single-center series, mortality risk in patients with RA with extra-articular manifestations was more than twice that of patients without extra-articular disease (relative risk [RR], 2.49; 95% confidence interval [CI], 1.43 to 4.03), and cardiovascular disease accounted for 70% of all deaths in this group.[60] Fortunately, clinically important extra-articular complications are decreasing, likely as a consequence of better treatment practices. However, some of our treatments may further complicate assessments for extra-articular complications in RA, because disease-remitting therapies can lead to adverse effects that closely mimic extra-articular disease manifestations. For example, glucocorticoids exacerbate both osteoporosis and cardiovascular disease risk, conditions already overrepresented in patients with RA. The focus of this section will be on the "true" extra-articular manifestations of RA, and not complications related to therapy, which are covered elsewhere in this textbook.

### Mucocutaneous

Rheumatoid nodules occur primarily in seropositive patients with active disease. In addition to RF positivity, a history of cigarette smoking appears to be a robust risk factor for the development of subcutaneous nodules in RA, particularly among men and heavy smokers.[61] When present and histologically confirmed, rheumatoid nodules are pathognomonic for RA. In rare circumstances, nodules may precede arthritis and may herald the development of other extra-articular manifestations when present early in the disease course. Rheumatoid nodules develop most commonly on extensor surfaces and pressure areas, including the forearm, Achilles and foot regions, and finger joints (Figure 70-9). The appearance of nodules in unusual sites can pose a significant diagnostic dilemma, with reports of rheumatoid nodules involving areas overlying the sacrum, sole and occiput (in bedridden patients), in addition to rare cases involving the heart, lungs (see the following discussion), sclera (rarely leading to perforation of the globe), and central nervous system.[62] In the larynx, rheumatoid nodules on the vocal cords may cause progressive hoarseness and mimic cricoarytenoid arthritis.

On examination, rheumatoid nodules are typically subcutaneous and firm and may be either mobile or adherent to underlying structures. Because the physical findings are nonspecific and subcutaneous nodules can be seen with other forms of inflammatory arthritis, biopsy may be needed to confirm the diagnosis in select circumstances. Other conditions that can result in inflammatory arthritis and nodules include rheumatic fever, tophaceous gout, SLE, and multicentric reticulohistiocytosis (Table 70-5). Histologically, rheumatoid nodules are characterized by a central area of necrosis rimmed by a corona of palisading fibroblasts, which are surrounded by a collagenous capsule with perivascular collections of inflammatory cells. These nodules grow by accumulating cells that expand centrifugally, leaving behind central necrosis of the connective tissue matrix. Inspection of early lesions suggests that the nodule is composed of small inflamed arterioles,[63] suggesting that rheumatoid nodules are a form of small vessel vasculitis. This fact may explain the relationship of this finding to other forms of extra-articular disease, such as cardiovascular disease. Although rheumatoid nodules may regress either spontaneously or with disease-remitting therapy, increased nodulosis is an uncommon but well-recognized complication of methotrexate treatment that often paradoxically occurs in patients with well-controlled disease.[64]

**Figure 70-9** Rheumatoid nodulosis on the extensor surface of the forearm **(A)**, the plantar aspect of the foot **(B)**, and the extensor surface of the fingers **(C)**. *(Courtesy Amy Cannella, MD.)*

Amyloidosis may also complicate long-standing inflammatory disease. The purpura of amyloidosis may be confused with the skin fragility and "senile purpura" seen in patients who have been on long-standing glucocorticoid therapy. Renal disease especially proteinuria or diarrhea with malabsorption in a patient with long-standing RA should prompt investigation for secondary amyloidosis.

Vasculitis in RA may present with multiple skin findings, ranging from relatively benign nail-fold infarcts to a deep, erosive, scarring pyoderma gangrenosum (see Vasculitis). The presence of livedo reticularis, with its characteristic lacey appearance (most prominent on the lower extremities), should raise a concern for a medium-vessel vasculitis or an associated connective tissue disease, such as SLE or anti-phospholipid antibody syndrome (APS).[65]

The prevalence of secondary Sjögren's syndrome (autoimmune exocrinopathy) has been estimated at 17%,[66] resulting in symptoms of keratoconjunctivitis sicca (dry eyes) or xerostomia (dry mouth). These symptoms are accompanied by objective evidence of lacrimal or salivary gland dysfunction. Finally, palmar erythema is often present in patients with active disease.

### Ocular

In addition to keratoconjunctivitis sicca, episcleritis and scleritis complicates the disease course in less than 1% of patients with RA. Episcleritis typically presents as a painless red eye without vision loss or frank discharge, the latter more indicative of conjunctivitis. Inspection reveals engorged blood vessels that move with light pressure and stop at the limbic border. Scleritis also results in scleral injection without discharge, but in contrast to episcleritis, this is typically accompanied by pain reported by the patient and precipitated by palpation of the globe, and may also be associated with areas of dusky discoloration. Manifesting with variable levels of involvement, scleritis can be localized and superficial or more generalized, and extend into deeper tissue layers. In severe cases, deeper involvement can be characterized by granulomatous scleral resorption leading to scleromalacia perforans (Figure 70-10). Whereas episcleritis can usually be managed with topical anti-inflammatory agents, scleritis treatment routinely requires systemic or intraocular immunomodulating therapy. In some cases, the sclera can become thinned, even in the absence of overt inflammation, and lead to scleromalacia.

Other forms of eye involvement in RA include chronic blepharitis or, rarely, perilimbic ischemic ulcers. This latter condition is caused by the deposition of cryoproteins (RF-IgG complexes), which can lead to perforation of the anterior chamber. Iritis and uveitis can occur in RA but are more commonly seen with other rheumatic conditions (e.g., spondyloarthropathies, sarcoidosis, Behçet's disease, and juvenile idiopathic arthritis).

**TABLE 70-5** Differential Diagnosis of the Rheumatoid Nodule*

| Diagnosis | Distinguishing Features |
|---|---|
| Rheumatic fever | Small in diameter (few mm to 1-2 cm), can be transient (rarely lasts >1 month); location more proximal over olecranon rather than proximal forearm; association with carditis |
| Granuloma annulare | Intracutaneous nodule; histologically identical to rheumatoid nodules; RF/ACPA$^-$ without synovitis |
| Xanthomatosis | Yellow tinged; often accompanied by high plasma lipoproteins and cholesterol levels |
| Gouty tophi | Often found in similar locations as RA nodules; aspiration and microscopic analysis which consists of collections of monosodium urate crystals; associated hyperuricemia; RF/ACPA$^-$ |
| Multicentric reticulohistiocytosis | Often located around the cuticles; histologically contain large, lipid-filled macrophages |
| Systemic lupus erythematosus | Accompanied by other signs and symptoms of active SLE (histologically similar to rheumatoid nodules) |

*Other less common disorders to consider include erythema elevatum diutinum, erythema nodosum, Gottron's papules, calcinosis associated with CREST (calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, telangiectasias), acrodermatitis chronica atrophicans, bejel, yaws, pinta, leprosy, and amyloid.

ACPA, Anti-citrullinated protein antibody; RF, rheumatoid factor; SLE, systemic lupus erythematosus.

## Bone

In addition to periarticular bone loss and local erosions, RA is a well-recognized cause of systemic bone loss, placing patients at a substantially higher risk for the development of osteoporosis and fracture. This risk is further heightened in the context of glucocorticoid therapy. In a prospective series of 395 patients with early RA, more than one-third experienced a fracture over just 5 years of follow-up.[67] In addition to glucocorticoid use, risk factors for bone loss and fracture in RA included older age, disability, longer disease duration, decreased grip strength, low body mass,[68] and increased inflammation.[69] Systemic inflammation in RA results in the increased expression of growth factors, including macrophage colony-stimulating factor (M-CSF) and receptor for activation of nuclear factor-κB ligand (RANKL), that promote osteoclast differentiation and ultimately bone resorption.[70] More recently, antigen-specific ACPA have been implicated as direct promoters of the osteoclastogenesis and bone loss that characterizes RA.[71] These findings are bolstered by animal work showing that immune responses to citrullinated self-antigen may serve as a trigger for declines in bone mineral density and bone quality.[72]

## Muscle

Weakness is a common patient complaint in RA. This may be related to associated joint pain and deconditioning or to type II muscle atrophy, complicating glucocorticoid use. There have been reports of inflammatory myopathy presenting with muscle tenderness and increased muscle enzymes. Muscle biopsies demonstrate focal accumulations of lymphocytes and plasma cells in a condition referred to as "nodular myositis." Necrotizing myositis has also been reported as a rare complication of RA.[73]

## Hematologic

Hematologic abnormalities are common in patients with autoimmune disease, and RA is no exception. Patients with RA frequently manifest a mild normocytic normochromic anemia that tends to correlate with increased disease activity and elevated inflammatory markers. Patients with chronic inflammation have an increased synthesis of ferritin and hemosiderin, abnormal retention of iron from senescent red blood cells, and increased lactoferrin, ultimately contributing to the binding and lowering of serum iron. Although mild anemia is common, the

presence of more severe anemia (i.e., hemoglobin <10 g/dL) suggests an alternative etiology. Mixed anemia poses a frequent diagnostic challenge in RA. For instance, a patient might have concomitant microcytic (iron deficiency or less commonly anemia of chronic disease) and macrocytic anemia (vitamin $B_{12}$ or folate deficiency, methotrexate use), a clinical scenario that is characterized by a heterogeneous red blood cell population (reflected in an increased red cell distribution width). In addition to its utility in evaluating causes of anemia, ferritin is an acute phase reactant and is therefore affected by inflammation. In general, however, a serum ferritin less than 50 ng/mL is indicative of iron deficiency, whereas values exceeding 100 ng/mL are indicative of adequate iron stores, regardless of RA disease activity.

Thrombocytosis is frequent with active RA, with platelet counts serving as an indirect measure of systemic inflammation. Platelet counts are positively correlated with both clinical and laboratory parameters of disease activity in RA, including ESR, RF, and several acute phase proteins.[74] Thrombocytopenia, on the other hand, is rare in RA in the absence of treatment-related bone marrow suppression or Felty's syndrome. As with other rheumatic and autoimmune conditions, eosinophilia may accompany active RA.

Associated with the presence of *HLA-DRB1*0401* allele,[75] Felty's syndrome comprises an uncommon but severe disease subset, defined by the triad of RA, splenomegaly, and leukopenia. The syndrome classically occurs in patients with long-standing disease, characterized by RF and ANA seropositivity and the presence of rheumatoid nodules and articular deformities, often in the context of minimal synovitis. In addition to rheumatoid nodules, these patients often have other extra-articular manifestations, and are at increased risk for bacterial infections and chronic nonhealing ulcers, leading to skin infections. The risk of bacterial infection is greatest in patients with more pronounced neutropenia (e.g., absolute neutrophil count [ANC] <100/$mm^3$). Low serum complements may also be seen in Felty's syndrome, with bone marrow biopsy typically yielding either normal or hyperplastic cell lines. In addition to associations with the HLA-DR*0401 allele, Felty's syndrome is characterized by the presence of autoantibodies directed against citrullinated histones that bind to activated neutrophils and neutrophil extra-cellular traps (NETs).[76]

Large granular lymphocyte (LGL) syndrome may also complicate the course of RA and may be related to Felty's syndrome. In addition to marked neutropenia, patients typically demonstrate LGL cells in both the blood and bone marrow. Splenomegaly may be variable.[77] LGL cells represent in vivo–activated cytotoxic T cells (CTC) or natural killer (NK) cells, and they proportionally represent 85% (CTC) and 15% (NK) of LGL syndromes, respectively.[78,79] LGL affects as many as 1% of patients with RA but is also seen in other inflammatory diseases (SLE, Sjögren's syndrome), viral infections, and hematologic malignancies (myelodysplastic syndrome). As opposed to aggressive and fatal subsets of LGL leukemia, the lymphocytosis associated with RA tends to follow an indolent course. In addition to rare malignant transformation, LGL places patients with RA at risk of infection. Although seemingly counterintuitive in the context of marked neutropenia, methotrexate remains the treatment of choice for both Felty's and LGL syndromes complicating RA. Splenectomy is reserved for those patients with Felty's syndrome and documented splenomegaly who are recalcitrant to medical management.

RA is associated with an increased risk of lymphoproliferative malignancy, particularly Hodgkin's disease and non-Hodgkin's lymphoma (NHL).[12] As with assessing the etiology of other extra-articular manifestations, delineating the simultaneous contributions of underlying RA from the effect of immunosuppressive agents used to treat the disease is difficult. Lymphoma risk in RA appears to be closely associated with RA disease activity and severity, even in the absence of RA treatments. In a large case-control study involving more than 11,000 patients with RA (many of whom were treatment naïve), those with higher levels of inflammation had a more pronounced risk of lymphoma, with an odds ratio of greater than 25 among those with the highest cumulative disease activity.[80] Patients with Felty's syndrome had an approximate 12-fold risk for lymphoma compared with patients with RA without this extra-articular manifestation.[81] In the absence of immunosuppressive therapy, RA results in the clonal expansion of $CD5^+$ cells, decreases the number and function of T-suppressor lymphocytes and NK cells, and inhibits T-suppressor function directed against the pro-oncogenic Epstein-Barr virus (EBV), which are all potential contributing factors to an increased lymphoma risk in RA.[12] These immunologic changes may also explain the general state of immunosuppression that characterizes RA even in the absence of immunomodulation therapy.

## Vasculitis

A small- to medium-vessel vasculitis can complicate the natural course of RA, a manifestation that is more common in men and associated with RF positivity (high titer), long-standing disease, and radiographic damage. Clinically, an important clue to the development of vasculitis is low serum complements with associated circulating immune complexes and cryoglobulins, along with the presence of other extra-articular manifestations.[82] Perhaps owing to improvements in treatment, the prevalence of rheumatoid vasculitis appears to have decreased substantially in recent years, with a study from the U.S. Veterans Health Administration showing a 20% to 50% drop in prevalence between 1997 and 2006.[83]

Rheumatoid vasculitis can present in a variety of ways, including:

- Distal arteritis with splinter hemorrhages, nail-fold infarcts, and possible gangrene (Figure 70-11)
- Cutaneous ulceration, including pyoderma gangrenosum
- Peripheral neuropathy with either a mononeuritis multiplex or a sensory-related stocking-glove polyneuropathy[84]
- Palpable purpura
- Arteritis involving viscera, similar to polyarteritis nodosum
- Rheumatoid pachymeningitis (rare), confined to the dura and pia matter

As with other forms of vasculitis, the signs and symptoms of systemic vasculitis in RA stem from vascular occlusion and resulting ischemic injury. Organ involvement is

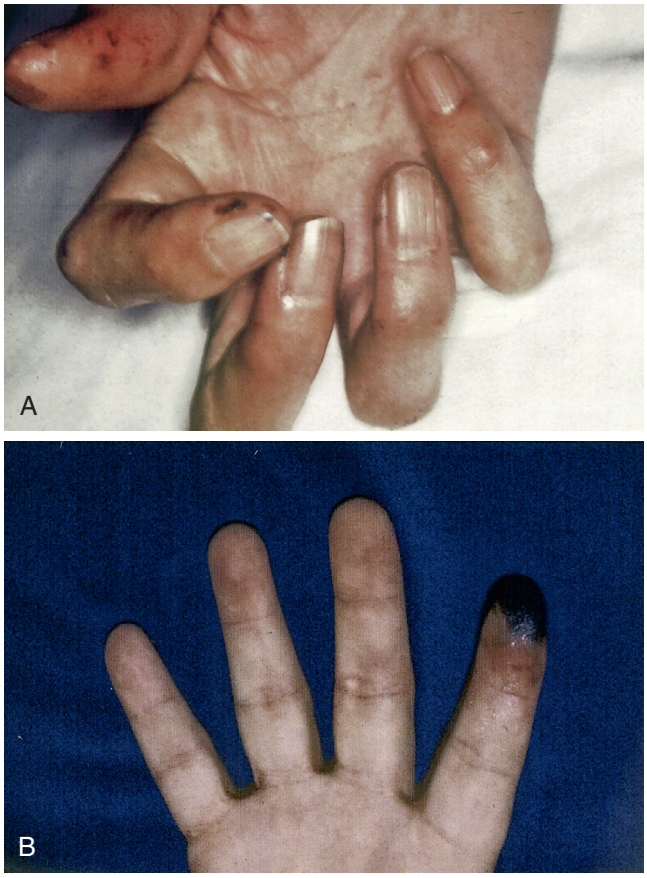

**Figure 70-11** **A**, Digital vasculitis with nail-fold infarcts in a seropositive patient. **B**, Digital gangrene of the index finger related to larger vessel involvement.

variable. Intestinal involvement typically manifests as abdominal pain with bowel infarction representing a surgical emergency. Digital gangrene, intestinal ischemia/infarction with bleeding or perforation, and mononeuritis multiplex are indicative of severe vasculitis and are associated with poor patient outcomes.[85,86] With diagnostic biopsy or tissue resection, histopathology in rheumatoid vasculitis typically demonstrates a "panarteritis" with fibrinoid necrosis. Obliterative endarteritis can be seen with distal gangrene, with the reported demonstration of immune complex deposition in the involved vessels.[87] As with other vasculitides, the treatment of rheumatoid vasculitis depends on the extent and severity of organ involvement. More conservative approaches can be used with splinter hemorrhage or palpable purpura in isolation, and more aggressive high-dose glucocorticoids and cytotoxic therapies are used for organ-threatening involvement.

## Pulmonary

Pulmonary involvement in RA is relatively common, with targets including the pleural or parenchymal tissue. Perhaps because of the increased prevalence of subclinical and clinical pulmonary involvement, patients with RA have a risk of lung cancer that is increased 1.5- to 3.5-fold versus that of the general population.[88] Although reported, clinically relevant small-airway disease and pulmonary hypertension appear to be relatively uncommon in RA,[89,90] and when present, appear to follow a relatively benign course. Several risk factors are associated with pulmonary complications related to RA, but some of the most important include smoking, RF and ACPA positivity, and being male.

**Pleural Disease.** Clinically apparent pleuritis may be evident in as many as 20% of RA cases, whereas postmortem examination suggests this number is higher. Pleural effusions in RA can be large and result in symptomatic dyspnea. Pleural effusions in RA are exudative, with mixed cell counts (predominance of monocytes), high protein and lactate dehydrogenase (LDH) levels, low glucose concentrations (resulting from a defect in the transport of glucose across the pleura), and low pH. Low pH and low fluid glucose, (10 to 50 mg/dL) are highly characteristic of RA-related effusions, although these values can also be observed in infectious etiologies (particularly tuberculosis).[91]

**Interstitial Lung Disease.** Pneumonitis and fibrosis are perhaps the most common and serious forms of pulmonary involvement in RA. On average, patients with RA complicated by ILD experience a 7-year reduction in median survival compared with patients with RA without lung disease.[92] With risk factors including male gender, smoking, older age at disease onset, and autoantibody (ACPA and RF) positivity,[93] ILD prevalence estimates vary widely across study populations, likely reflecting important differences in methods of case ascertainment. The clinical course of ILD in RA is also highly variable, ranging from an asymptomatic and indolent course to rapidly progressive and life threatening in a minority of patients. Radiographs typically demonstrate bibasilar reticular or reticulonodular patterns in both lung fields, with a characteristic honeycombing appearance in more advanced disease. HRCT and lung biopsy remain the gold standard for evaluation. Usual interstitial pneumonia (UIP) is the most common pattern seen on HRCT, with biopsy results showing diffuse fibrosis often in the midst of a mononuclear cell infiltrate (lymphocytes, plasma cells, and histiocytes). Even with limited disease, pulmonary function tests frequently reveal a decreased diffusion capacity with evidence of volume restriction (e.g., diminished vital capacity) becoming evident with more extensive ILD.[93,94]

Caplan's syndrome[95] represents a rare complication of RA, in which extra-articular ILD acts in concert with a pneumoconiosis (related to coal, silica, or asbestosis exposure) to produce a rapidly progressive obliterative granulomatous fibrotic syndrome. Lymphoid interstitial pneumonitis (LIP), a benign lymphoproliferative disorder of the lung, has been observed in patients with RA and Sjögren's syndrome.[96] Characteristic HRCT findings of LIP include ground-glass changes accompanied by thickened bronchovascular bundles, small ill-defined pulmonary nodules, and scattered thin-walled cysts within the lung parenchyma in a perivascular or subpleural location. Consistent with a lymphoproliferative process, approximately 80% of patients with LIP have evidence of a polyclonal or monoclonal IgM gammopathy.[97] Obliterative or constrictive bronchiolitis is an uncommon and severe form of interstitial pneumonitis that progresses to alveolar involvement and bronchiolitis, respiratory failure and, in some cases, death. Pathologically, bronchiolitis is characterized by fibroblast proliferation with proteinaceous exudates and interstitial infiltrates. The course and prognosis is distinct from cryptogenic organizing

pneumonia (COP) (also known as idiopathic bronchiolitis obliterans with organizing pneumonia) and nonspecific interstitial pneumonitis (NSIP), both of which are more responsive to immunosuppression than either UIP or bronchiolitis.

**Obstructive Lung Disease.** Although its links with restrictive lung disease has been long recognized, recent attention has focused on associations of RA with obstructive lung disease (OLD). In a recent population-based study from the Rochester Epidemiology Project, OLD was approximately 50% more likely to develop in individuals with RA than in controls, even after adjusting for age, gender, alcohol use, and smoking history (hazard ratio [HR], 1.54; 95% CI, 1.01 to 2.34).[98] In this cohort, chronic obstructive pulmonary disease (COPD) was the most prevalent form of OLD, with asthma and bronchiectasis far less common. Risk factors independently associated with the development of OLD among patients with RA included smoking, RF positivity, increased ESR, and a history of prior disease-modifying anti-rheumatic drug (DMARD) and steroid use.

**Nodular Lung Disease.** Rheumatoid nodules can develop in the pulmonary parenchyma, presenting either singly or in clusters, and serve as a hallmark of Caplan's syndrome, as already detailed. Characterized by central necrosis, pulmonary nodules from RA can cavitate, leading to the formation of bronchopleural fistulas. Although a core needle biopsy can be used for evaluation, particularly in the context of a solitary pulmonary nodule, a more aggressive diagnostic strategy may be warranted when results are equivocal or the patient is otherwise deemed to be "high-risk," recognizing that pulmonary nodulosis and bronchogenic carcinoma have been reported to co-exist in RA.[99]

### Cardiovascular

Cardiovascular disease (CVD) is common, representing the leading cause of excess mortality in RA. In addition to associations with atherosclerosis and coronary artery disease, extra-articular cardiac manifestations also relate to serositis, valvulitis and fibrosis.

**Atherosclerosis.** Patients with RA are disproportionately impacted by CVD outcomes,[100-102] including angina, myocardial infarction (MI), congestive heart failure (CHF), stroke, and the need for coronary revascularization. In a large prospective study, patients with RA were approximately twice as likely as individuals without RA to develop CHF.[102] Likewise, the rate for MI and stroke in RA are also approximately twofold higher than that of individuals without RA, as assessed in a cohort study of more than 25,000 patients with RA.[103] A recent meta-analysis noted a 50% increase in CVD-related mortality, with a 52% increase in death from cerebrovascular disease as well as a 59% increase in death from ischemic heart disease among patients with RA compared with non-RA controls.[100] The increased risk of CVD in RA appears to be independent of traditional risk factors such as hypertension, hyperlipidemia, and diabetes.[104]

The premature atherosclerosis and resulting CVD risk observed appears to be a consequence of the systemic inflammatory burden posed by RA. Several studies have now demonstrated that greater levels of RA disease activity, including both ESR and CRP, are robust predictors of major acute cardiac events.[105,106] These data underscore the potential importance of disease-remitting therapy, not only as a means of improving articular symptoms of RA, but also of mitigating CVD outcomes. In addition to associations with higher acute phase responses, both RF[107] and ACPA[108] positivity are associated with increased CVD. Although mechanisms linking autoantibody status to CVD have not been well elucidated, recent data from Sokolove and colleagues have shown that citrullinated autoantigens are expressed in atheromatous plaque.[109] Moreover, ACPA targeting citrullinated forms of fibrinogen and vimentin are associated with aortic plaque burden in patients with RA.

**Pericarditis.** Pericarditis is the most common cardiac manifestation of RA and may be seen in as many as 50% of patients at autopsy. Clinically apparent disease is far less common, with cardiac tamponade serving as a rare consequence. With RA involvement, pericardial fluid demonstrates findings similar to that described with RA-related pleuritis; an exudative sample characterized by cellular infiltrate, high protein and LDH concentrations, and a low glucose and low pH. Rarely, constrictive pericarditis can complicate the course RA and may require pericardectomy or pericardial stripping for definitive treatment.[110]

**Myocarditis.** Myocarditis is rare but may be related to granulomatous disease or interstitial myocarditis. The granulomatous process, when present, pathologically resembles rheumatoid nodules and is highly specific for RA.

**Conduction Defects.** Atrioventricular (AV) block is an unusual complication of RA, but if present is probably related to direct granulomatous involvement. Complete heart block has been described and is also more common in patients with seropositive nodular disease.[111] Because RA is a chronic inflammatory process, patients with long-standing, poorly controlled disease are at risk for amyloidosis, which can result in both cardiomyopathy and conduction disturbances.

**Endocardial Inflammation and Granulomatous Aortitis.** Often asymptomatic, echocardiographic studies have demonstrated a high prevalence of mitral valve abnormalities in RA.[112] Although more commonly associated with ankylosing spondylitis, aortic valve disease has also been observed as a consequence of RA.[113] In severe RA, granulomatous disease of the endocardium can spread to the base of the aorta resulting in aortitis and valvular incompetency, which can rarely necessitate emergent valve replacement.[114]

### Prognosis and Individual Patient Follow-up

Several factors have been associated with poor outcomes in RA. These outcomes are defined by reduced survival and increases in disability, related health care costs, the accrual in structural joint damage, and the need for total joint arthroplasty. Some of the factors that have been associated with poor outcomes include:

- Autoantibody (RF and ACPA) positivity[14-16]
- Measures indicative of greater disease activity at baseline[16]
- Extra-articular disease[14]
- Longer disease duration[16]
- Diagnostic and treatment delays[115]
- *HLA-DRB1* shared epitope status[116]

- Cigarette smoking and heavy alcohol use[14,117]
- Occupational factors and socioeconomic status[9]
- Erosive disease[116]
- Comorbid illnesses, including depression, post-traumatic stress disorder, and others[14,16,118]

Recent ACR treatment guidelines "risk-stratify" patients based on characteristics such as RF or ACPA positivity or the presence of radiographic erosions. It is important to recognize, however, that although these factors may be statistically correlated with select outcomes in RA, none of these (either alone or in combination) have been demonstrated to provide robust predictions of any outcome at the level of the individual patient. As emphasized in Chapter 71, improved outcomes have increasingly been achieved through the adoption of a treat-to-target strategy in RA management, an approach that is built on a foundation of routine follow-up accompanied by systematic disease activity assessments and treatment modifications as required to achieve a state of either low disease activity or remission. Through these efforts, we are also realizing fewer extra-articular complications to include fewer meaningful vascular complications.

CHAPTER 71

# Treatment of Rheumatoid Arthritis

James R. O'Dell

**KEY POINTS**

- Rheumatoid arthritis (RA) should be diagnosed early, and disease-modifying anti-rheumatic drug (DMARD) therapy should be initiated at the time of diagnosis.
- Treatment for all patients should be based on a disease activity target—either remission or low disease activity.
- The type of DMARD therapy the patient receives is not as important as ensuring that the treatment meets the disease activity target.
- The initial DMARD and the cornerstone of therapy for most patients is methotrexate.
- Many patients will require combinations of DMARDs with or without biologic agents to achieve the disease activity target.
- Many very effective biologic DMARDs are available; essentially all DMARDs are more effective when administered with methotrexate.
- Nonsteroidal anti-inflammatory drugs may provide useful symptom control but are rarely indicated without concomitant use of DMARDs.
- Glucocorticoids are rapidly effective DMARDs but have adverse effects. Therefore they should be used only with other DMARDs and ideally only as a bridge to effective DMARD therapy.
- The ubiquitous comorbidities of RA—particularly cardiovascular disease—must be addressed aggressively.

The treatment of rheumatoid arthritis (RA) has evolved dramatically during the past 30 years, perhaps more so than for any of the other rheumatic diseases. Every rheumatologist who has had the privilege of caring for patients with rheumatoid disease during that period will immediately and enthusiastically acknowledge how far we have come. **The majority of patients newly diagnosed with RA can expect to experience remission of their disease if it is treated early in the disease process by a rheumatologist.** This outcome is remarkable, and it is appropriate to take a step back and examine the reasons behind this sea change. Many persons quickly point to the fact that biologic agents became available in 1998, and they quickly allocate the lion's share of the credit for the dramatic improvement in outcomes to these remarkable medications. Statements such as, "Since the biologics have come on the market, results have improved dramatically" are commonplace. It is clear that this progress in treatment got a tremendous boost with approval of biologic agents almost 20 years ago. Biologic agents are very effective, and importantly, they have helped invigorate clinicians and patients alike, making both parties believe that higher expectations regarding control of RA are justified. However, it is important to acknowledge all the other changes that occurred in roughly that same time frame and have been universally embraced by rheumatologists (Table 71-1).

It is difficult if not impossible to know which of these changes, all of which have become accepted in the past quarter century, are most important. Clearly, early diagnosis aided by use of anti-citrullinated protein antibodies (ACPAs) and the new classification criteria are critical.[1] The universal acceptance that all patients with RA should be taking a disease-modifying anti-rheumatic drug (DMARD)[2-5] and the effective use of increasing doses of methotrexate (MTX) with folic acid have also played huge roles. Additionally, in the mid-1990s, the use of combination DMARDs became an accepted strategy.[6] Early diagnosis, effective use of MTX and combination DMARDs, and biologic agents are the tools that allow us to do the job. **Treat to target (T2T) defines what that job is**. Therefore T2T arguably has been the most important factor in improved outcomes in RA. The Tight Intensive Control of RA (TICORA) trial (discussed in more detail in a subsequent section of this chapter) was the seminal study that put T2T on the map, because it dramatically demonstrated the benefits of this approach.[7] The TICORA trial demonstrated that if patients are treated aggressively to achieve remission or low disease activity, the outcomes improve significantly both clinically and radiographically, even without the use of biologic agents. Similarly, in the Dutch Behandel-Strategieen (BeSt) study, the aggressive use of therapeutic adjustment (T2T) led to significant clinical improvement regardless of the initial choice of drugs, which included both biologic agents and conventional regimens.[8] Therefore **the most important tenet of successful RA therapy today is not which of the score of DMARDs, conventional or biologic, are used (Table 71-2) but that all patients are treated to meet the disease activity target.**

Despite how far we have come, many challenges remain, including first and foremost the identification of markers that predict in a differential fashion who will respond to or experience adverse effects from which treatment, along with further developing methods to allow us to measure the amount of immunosuppression that our agents are producing so we can titrate doses appropriately.

In this chapter the following topics will be discussed: the broad principles of treatment, the goals of RA therapy, the timing of different therapies, and the strategies of using the plethora of options now available to achieve the best

disease control for each patient. Most of the drugs themselves will not be covered in detail here; rather, this chapter will focus on strategies. Please refer to the many other excellent chapters in this book for specific information on nonsteroidal anti-inflammatory drugs (NSAIDs; Chapter 59), glucocorticoids (Chapter 60), traditional DMARDs (Chapter 61), immunoregulatory drugs (Chapter 62), anticytokine therapies or biologic agents (Chapter 63), and the new Janus kinase (JAK) agents (Chapter 65).

## GOAL OF RHEUMATOID ARTHRITIS TREATMENT

It is truly remarkable that rheumatologists now have more than 20 approved conventional or biologic DMARDs from which to choose (Table 71-2). However, as previously noted, despite all these terrific DMARD options, **the most important paradigm shift for the treatment of RA has been the realization that patients should be treated early and with a target of low disease activity or remission.**[2-5,7] For persons outside the rheumatologic community, this seems like stating the obvious—if patients have hypertension, hyperlipidemia, or diabetes, they are of course treated so that their blood pressure, low-density lipoprotein, or glycosylated hemoglobin (HbA1c) levels, respectively, are reduced to a defined and easily measured goal. The problem with RA has been the lack of valid reproducible measures of disease activity and remission that can be routinely measured and followed up on in the clinic. Unfortunately, no single examination finding or laboratory test satisfactorily measures disease activity in persons with RA.

Many measures have been proposed,[9-15] all of which are composite measures that include information derived from some combination of joint examinations, patient and physician assessment of disease activity, patient function, and laboratory measures of inflammation (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP] levels). Recently the American College of Rheumatology (ACR) has endorsed a list of disease activity measures that have been shown to correlate with outcomes. Table 71-3 is a partial list of some of the better known of these measures. Each of these measures has strengths and weaknesses[15]; some rely only on data from the patient, some require complete joint counts by clinicians, and some require laboratory tests to measure inflammation. Busy clinicians rarely have time to document disease activity in more than 60 tender and swollen joints or wait for laboratory test results to make treatment decisions during a patient's visit. Therefore measures that simplify this process as much as possible are being embraced, including measures that limit the joints that are examined to 28 (Disease Activity Score in 28 joints [DAS28]), do not require laboratory tests (Clinical Disease Activity Index), or are entirely dependent on patient-reported data (Routine Assessment Patient Index Data). A high correlation exists among these measures, and thus currently in the clinic **it is very important that disease activity be measured and less important which measure is used.**

Because none of our therapies cure RA, it would seem obvious that the next best goal should be remission. However, the concept of remission as a goal for patients with RA is problematic. First, a definition of remission that is both relevant and practical has been elusive. To be relevant, remission should be highly predictive of the absence of disease progression over time. To be practical for

**TABLE 71-3** Instruments Used to Measure Rheumatoid Arthritis Disease Activity

| Instrument | Score Range | Remission | Thresholds of Disease Activity | | |
|---|---|---|---|---|---|
| | | | Low | Moderate | High |
| Disease Activity Score in 28 joints (DAS28) | 0-9.4 | ≤2.6 | ≤3.2 | >3.2 and ≤5.1 | >5.1 |
| Simplified Disease Activity Index (SDAI) | 0.1-86.0 | ≤3.3 | ≤11 | >11 and ≤26 | >26 |
| Clinical Disease Activity Index (CDAI) | 0-76.0 | ≤2.8 | ≤10 | >10 and ≤22 | >22 |
| Rheumatoid Arthritis Disease Activity Index (RADAI) | 0-10 | ≤1.4 | <2.2 | 2.2 and ≤4.9 | >4.9 |
| Patient Activity Scale (PAS or PASII) | 0-10 | ≤1.25 | <1.9 | ≥1.9 and ≤5.3 | >5.3 |
| Routine Assessment Patient Index Data (RAPID) | 0-30 | ≤1 | <6 | ≥6 and ≤12 | >12 |

**TABLE 71-4** American College of Rheumatology/European League Against Rheumatism Definitions of Remission in Rheumatoid Arthritis Clinical Trials

| |
|---|
| **Boolean-Based Definition** |
| At any time point, the patient must satisfy all of the following: |
| Tender joint count ≤1* |
| Swollen joint count ≤1* |
| C-reactive protein ≤1 mg/dL |
| Patient global assessment ≤1 (on a 0-10 scale) |
| **Index-Based Definition** |
| At any time point, the patient must have a Simplified Disease Activity Index score of ≤3.3. |

*Include 28 joints plus feet and ankles.

From Felson DT, Smolen JS, Wells G, et al: American College of Rheumatology/European League against Rheumatism provisional definition of remission in rheumatoid arthritis for clinical trials, *Arthritis Rheum* 63:573–586, 2011.

clinicians, a definition of remission should be easy to apply in real time to patients seen in the clinic, as previously discussed with regard to measures of disease activity. A new definition of remission for use in clinical trials has been developed by a joint ACR and European League Against Rheumatism (EULAR) effort (Table 71-4[1]). This definition has been rigorously tested against short-term radiologic outcomes in 1- to 2-year randomized controlled trial (RCT) follow-up. This definition standardizes remission and therefore is a huge step forward for reporting and comparing results across clinical trials.

However, this definition was designed for clinical trials and not for clinical care,[16] where rigorous counts of joints with disease activity are not always performed and the need to have CRP results in real time becomes a major problem for clinical work flow. Versions of disease activity scales that do not require laboratory values have been suggested but have not been fully accepted (e.g., the Clinical Disease Activity Index and Patient Activity Scale). Perhaps more problematic is that many persons who believe that remission is defined by clinical data alone will always underestimate the amount of low-level disease activity that could be found if synovial biopsies or advanced imaging techniques such as ultrasound or magnetic resonance imaging (MRI) were used. Significant data indicate that many and perhaps most patients with RA who meet the definitions of "remission" are found to have active disease when they are assessed by ultrasound or MRI.[17-19] Recently it was reported that all patients believed to be in clinical remission during the Treatment of Early Aggressive Rheumatoid (TEAR) trial (discussed in detail in a subsequent section of this chapter) had evidence of inflammation on MRI scans.[20] Indeed, the newly accepted ACR/EULAR definition allows for a swollen joint, which many persons would argue is not really full clinical remission. Another major problem with the term "remission" is that, according to currently available data, **it is not at all clear that remission, regardless of how it is defined, should be the treatment goal for all patients with RA**.

Many patients do very well despite having low levels of disease activity. This situation may be analogous to the recent studies that show that pushing HbA1c levels below 6.5, which seemed appropriate for diabetic control, was associated with increased cardiovascular mortality, mainly as a result of hypoglycemia in patients with histories of cardiovascular disease.[21] **The following important question remains unanswered: In RA, where is the tipping point between pushing the disease activity ever lower and the toxicity and cost of doing so?** To further complicate matters, it is almost guaranteed that the tipping point will be different for each patient. The following issues need to be considered:

- When do the risks and considerable expense of some of our RA therapies outweigh the benefits of escalating therapy further?
- Which patients who have improved dramatically but still have two tender or swollen joints need to switch to a third biologic agent?
- With regard to the aforementioned diabetic patients with cardiovascular disease, which patients with RA are most at risk for toxicities if we push too hard for remission?
- Finally, with current therapies, the vast majority of remissions in persons with RA require ongoing treatment with DMARDs, so the concept of a true remission—meaning one where no therapy is required—remains beyond our current reach for most patients.

Despite the problems in defining remission or low disease activity, **it is clear that patients do better when clinicians have a goal.** The Scottish TICORA study[7] was the first to convincingly demonstrate this concept in a randomized fashion. In this study, patients who had disease for fewer than 5 years were randomized to receive either routine care or intensive care. Both groups were treated with an algorithm of conventional DMARDs (Figure 71-1A). The routine care group had regular follow-up and monitoring, whereas the intensive group was seen monthly and underwent proscribed escalation of therapy (per a protocol) if they had not achieved the goal of low disease activity (defined in this study as Disease Activity Score [DAS] of ≤2.4). Both groups improved significantly, but the T2T group (i.e., the intensive group) did significantly better, with mean DAS scores (1.6) in the remission range at 18 months (Figure 71-1B). In the intensive group, 71% of subjects achieved an ACR 70% composite improvement (ACR70) compared with 18% in the routine care group ($P$ <0.0001). Further, this clinical improvement translated to significantly less radiographic progression of erosions compared with the routine care group (0.5 vs. 3.0; $P$ = 0.002). Importantly, this improved disease control was not associated with an increase in treatment-associated adverse events. Finally, although it entailed more frequent visits, intensive therapy resulted in a cost savings even in the short term. These results were particularly remarkable considering that they were obtained using conventional DMARDs alone (Figure 71-1A), without use of biologic agents. Findings from other studies have corroborated these findings.[8,22,23] Further, a meta-analysis of tight control strategies[24] has suggested that tight control strategies work best if they are performed according to a protocol, as occurred in the TICORA study.

Although the TICORA investigators selected low disease activity as the target, the target could have been remission, as was previously discussed. Most of the

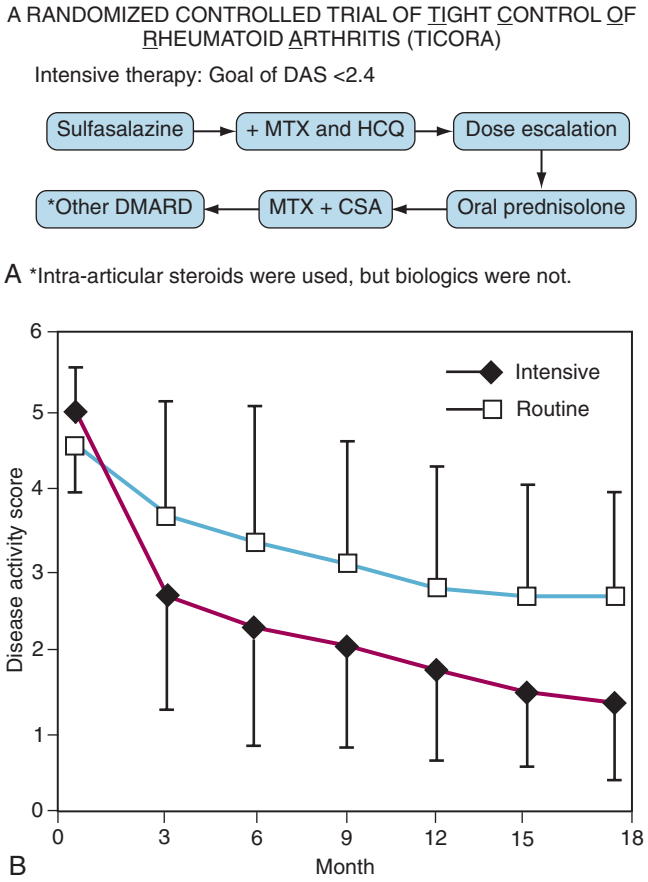

**Figure 71-1** **A,** Treatment escalation used in the Tight Intensive Control of RA (TICORA) trial. **B,** Comparison of intensive and routine treatment groups. CSA, Cyclosporine A; DAS, Disease Activity Score (in 44 joints); DMARD, disease-modifying anti-rheumatic drug; HCQ, hydroxychloroquine; MTX, methotrexate. *(Modified with permission from Grigor C, Capell H, Stirling A, et al: Effect of a treatment strategy of tight control for rheumatoid arthritis [the TICORA study]: a single-blind randomized controlled trial,* Lancet *364:263–269, 2004.)*

aforementioned endorsed measures of disease activity have defined levels that signify "remission" (see Table 71-4). Predictably, the harder we push for remission with increasing numbers and doses of DMARDs, both conventional and biologic, the more that the toxicity and expense (Table 71-5) of our treatments become a concern. Both the ACR and EULAR guidelines, as well as recent reviews,[2-5] state that low disease activity or remission are the goal and leave the decision about which goal is most appropriate for each unique patient's situation to the clinician. **Therefore, until further data elucidate this question, clinicians will need to continue to practice both the art and the science of medicine when selecting the most appropriate target for each patient.**

## CLASSES OF DRUGS

### Disease-Modifying Anti-rheumatic Drugs

#### Methotrexate, Sulfasalazine, Hydroxychloroquine, Leflunomide, and Azathioprine

By definition, a DMARD has the ability to change the course of RA (for the better). The most rigorous application of this definition requires RCTs to show that a DMARD has the ability not only to change the clinical course of the disease but also to decrease or halt the radiographic progression. By this definition, all of the 11 conventional DMARDs and the 9 biologic DMARDs listed in Table 71-2 qualify, with the possible exception of minocycline and hydroxychloroquine (HCQ), for which only weak evidence of radiographic benefits exists. When the DMARDs listed in Table 71-2 are used individually or in combinations of two, three, or four, as is often the case, more than 4000 possible combinations exist for each individual patient, assuming that biologic agents are not used in combination. Obviously, this huge number of choices is both good news and bad news for the clinician; it is great to have all the options but impossible to keep them all straight. Therefore, to use these drugs effectively, the clinician must have goals, strategies, and an up-to-date knowledge of the drugs and their interactions and toxicities.

The most widely used conventional DMARDs—MTX, sulfasalazine (SSZ), HCQ, and leflunomide (LEF)—are discussed in detail in Chapter 61. Together, these four DMARDs, along with glucocorticoids (see Chapter 60), currently account for the vast majority of conventional DMARD use. The new player in this arena is tofacitinib (see Chapter 65); its potential niche in the treatment of RA will be discussed in a subsequent section of this chapter. Although less commonly used, azathioprine, cyclosporine, and the tetracyclines (minocycline and doxycycline) remain important as niche therapies. They are not covered elsewhere in this book and thus will be discussed here. Gold, which has been used in the treatment of RA for more than a century, is an effective therapy, particularly if used intramuscularly,[25-29] but it is cumbersome to administer and has a narrow therapeutic window. At present it is used so rarely that it will not be discussed for the first time in the history of this textbook. Penicillamine is of historical interest[30] but is rarely used and will not be discussed in this chapter.

**TABLE 71-5** Costs of Disease-Modifying Anti-rheumatic Drugs in the United States in 2015

| Medication | Cost |
|---|---|
| **1 Month oral DMARD from Walgreen's** | |
| Methotrexate #32, 2.5-mg tablets | $101 |
| Hydroxychloroquine, 200 mg, #60 | $222 |
| Sulfasalazine, #120, 500-mg tablets | $33 |
| Tofacitinib (Xeljanz), 5 mg, #60 tablets | $3002 |
| Etanercept, 50 mg, syringe #4 | $4082 |
| Adalimumab, 40 mg, syringe #2 | $4224 |
| Adalimumab, 40 mg, pen #2 | $4224 |
| **1 Month IV DMARDs from Good RX*** | |
| Infliximab, 300 mg | $3180 |
| Rituximab, 1500 mg | $2350 |
| Abatacept, 750 mg | $2200 |
| Tocilizumab, 400 mg | $1650 |

*Mean of available data (medication only, not infusion price).
DMARDs, Disease-modifying anti-rheumatic drugs; IV, intravenous.

### Biologic Disease-Modifying Anti-rheumatic Drugs

The biologic DMARDs are discussed in detail in Chapter 63. Within this class of agents we now have the ability to inhibit multiple inflammatory cytokines, including TNF, which is inhibited with three monoclonal antibodies, infliximab, adalimumab, and golimumab; the TNF receptor protein, which is inhibited with etanercept (ETAN); the pegylated Fab fragment, which is inhibited with certolizumab; IL-1, which is inhibited with the IL-1 receptor antagonist anakinra; and IL-6, which is inhibited by the monoclonal antibody to the IL-6 receptor, tocilizumab. We also have the ability or to kill or inhibit cell lines important in inflammation, including B cells (with rituximab) and T cells (with abatacept). **It is an understatement to say that biologic agents have changed the landscape of RA therapy forever** both in terms of therapeutic expectations and the understanding of RA pathogenesis, but as previously discussed, it is also important to acknowledge that they are not the only game changer (see Table 71-1). Because of their often quick onset of action, particularly with the TNF inhibitors and tocilizumab, and their ability to retard radiographic progression of disease, they are increasingly used earlier and more often in persons with RA. The challenge for clinicians is to appropriately integrate conventional and biologic therapies and to use biologic agents when necessary but to make sure the much less expensive conventional therapies have been optimized.

### Glucocorticoids

Glucocorticoids, which are discussed in detail in Chapter 60, have a long and storied history in the treatment of RA. RA was selected as the first disease to be treated with "compound E" at the Mayo Clinic in 1948, and the rest is history.[31] Responses were both rapid and dramatic; an analysis of the first 14 patients treated revealed that in 100%, ESRs improved by more than 50% within 1 to 3 months, and in 80%, ESRs improved by at least 70% (an ESR of 70 is a convenient ACR70). Several landmark studies have proved not only clinical efficacy[32-37] but also the significant radiographic efficacy of glucocorticoids.[35,37] The recent Combinatie therapie Bij Rheumatoide Artritis (COBRA) trial[36,37] and the COBRA arm of the BeSt study (discussed in a subsequent section of this chapter[8,22]) again demonstrated the significant clinical and radiographic benefit that glucocorticoids can provide. However, despite their rapid onset and all the other positive benefits of glucocorticoids in RA, their toxicities are also legend.

Currently glucocorticoids are most often and most appropriately used along with DMARDs as part of initial "induction" therapy to gain rapid control of RA, and then they are aggressively tapered as the slower-acting DMARD starts to kick in. Recent data suggest that patients whose treatment is initiated with the combination of MTX and prednisone initially have better results than do patients who take MTX alone.[38] Historically, the belief has been that once a patient with RA began taking glucocorticoids, he or she would never be able to stop using them. This scenario is clearly not true because of the effective DMARDs that are now available, and successful tapering of glucocorticoids is now the rule.[8,22,39] The inability to taper glucocorticoids successfully or at least to taper them to an "acceptable" low dose is a strong indication that the current DMARD program is not working. Long-term use of doses equivalent to prednisone of greater than 7.5 to 10 mg per day is a clear indication that DMARD therapy needs to be escalated. Importantly**, glucocorticoids should almost never be used to treat RA without concomitant use of DMARDs.**

### Other Conventional Disease-Modifying Anti-rheumatic Drugs

**Azathioprine.** Azathioprine (AZA), 50 to 200 mg/day, has been used to treat RA for more than 50 years. Because it has been a generic drug for many years, little recent research has been performed on AZA. Although clearly it is not a first-line DMARD in contemporary RA treatment, AZA is most commonly used as a substitute for MTX when contraindications or intolerance to MTX exist. Arguably, all the biologic agents work better with concomitant use of MTX, and this phenomenon is particularly true of the TNF inhibitors. One reason for the increased efficacy of TNF inhibitors with concomitant use of MTX is the ability of MTX to prevent the formation of antidrug antibodies. A recent meta-analysis has shown that whereas MTX is most effective at preventing the formation of these antibodies (providing protection at the 77% level), AZA also does so at about the 50% level.[40] Therefore, when patients are being treated with monoclonal antibody therapies and cannot tolerate MTX, the use of AZA should be strongly considered. This situation most commonly arises in patients with the so-called "MTX flu," but other situations, including pregnancy and liver, pulmonary, or renal disease, may be indications for use of AZA in persons with RA. A particularly problematic patient population is patients with RA, frequently male, who have RA interstitial lung disease. Use of MTX and LEF may be problematic, and AZA becomes the best conventional DMARD choice. Currently, AZA is usually used in combination with other conventional or biologic DMARDs. McCarty, who was one of the pioneers of combination therapy in RA, has with several colleagues reported on the combination of MTX, AZA, and HCQ in 69 patients treated in an open-label fashion.[41] With this combination, 45% of patients reached remission according to the previous ACR criteria, and this combination was well tolerated. Further, the combination of low doses of AZA and MTX was more effective than higher doses of either drug alone, although this difference did not reach statistical significance in an underpowered study.[42]

Neutropenia is the most common complication of AZA treatment. Neutropenia can be predicted with a genetic test for polymorphisms of the enzyme thiopurine methyltransferase. Patients who are homozygous for the mutant polymorphism that is nonfunctional (1 in 300 or 0.3% of patients) are very sensitive to bone marrow and other toxicities of AZA. Patients who are heterozygotes (perhaps 10% of the population) may have milder neutropenia.[43] Unfortunately, this test is expensive; in some centers it may cost up to a $1000, and reimbursement is not always assured. Some clinicians elect to start with low doses of 50 mg/day, check complete blood cell counts at 2 weeks, and then increase the dose as needed if the white blood cell count is acceptable. It has been speculated that the subset of patients

with the nonfunctional polymorphisms could be the patients who, when AZA was added to a stable MTX regimen, experienced an acute febrile toxic reaction characterized by fever, leukocytosis, and a cutaneous leukocytoclastic vasculitis.[44]

**Cyclosporine.** In the 1990s, cyclosporine (CSA) gained a foothold in the treatment of RA.[45] CSA, which is mostly used in transplantation procedures to prevent allograft rejection, inhibits the activation of $CD4^+$ helper-inducer T lymphocytes by blocking IL-2 and other T helper type 1 cytokine production[46] and by inhibiting CD40 ligand expression in T lymphocytes.[47] The latter effect prevents T cells from delivering CD40 ligand-dependent signals to B cells. Interest in CSA peaked in the mid-1990s when Tugwell and colleagues[48] showed that the addition of CSA (2.5 to 5 mg/kg/day) to a stable dose of MTX provided substantial additive benefit compared with MTX alone. In the CSA + MTX group, an ACR 20% composite improvement (ACR20) was achieved by 48% of subjects, compared with 16% of subjects for the placebo group (Figure 71-2). Additionally, this therapy seemed to slow radiographic progression of erosions.[49] In this trial, the dose of CSA was decreased if the patient's creatinine level increased to more than 30% of initial values. Unfortunately, follow-up reports revealed that only 22% of patients continued taking this combination at 18 months, with the most common reasons for discontinuation being hypertension or increasing creatinine levels.[49] Treatment of patients with hepatitis C and RA may provide a niche for CSA, because it has anti-viral activity against hepatitis C.[50,51]

## Minocycline and Doxycycline

Tetracycline and its derivatives have a long and somewhat checkered history with regard to the treatment of RA and other arthritidies.[52,53] They are not mainstream therapy for RA but may have a niche in patients for whom laboratory monitoring is not feasible, in patients with frequent infections, or in patients who have concomitant periodontal disease. The mechanism of action of tetracyclines in RA is poorly understood. Tetracyclines are, of course, antibiotics, but they also inhibit metalloproteinases, modulate immune responses, and have anti-inflammatory effects. No evidence exists to support the claim that tetracyclines treat the "infection that causes RA," as was touted by some of the original supporters of this drug.[53] However, it is entirely possible that inhibition of nonspecific infections that upregulate the immune response via IL-1, TNF, and IL-6, such as periodontitis, bronchitis, and gastritis, to name a few, may be helpful in controlling disease in patients with RA.

Increasingly, the microbiome and the role it may be playing in RA pathogenesis, disease activity, and responses

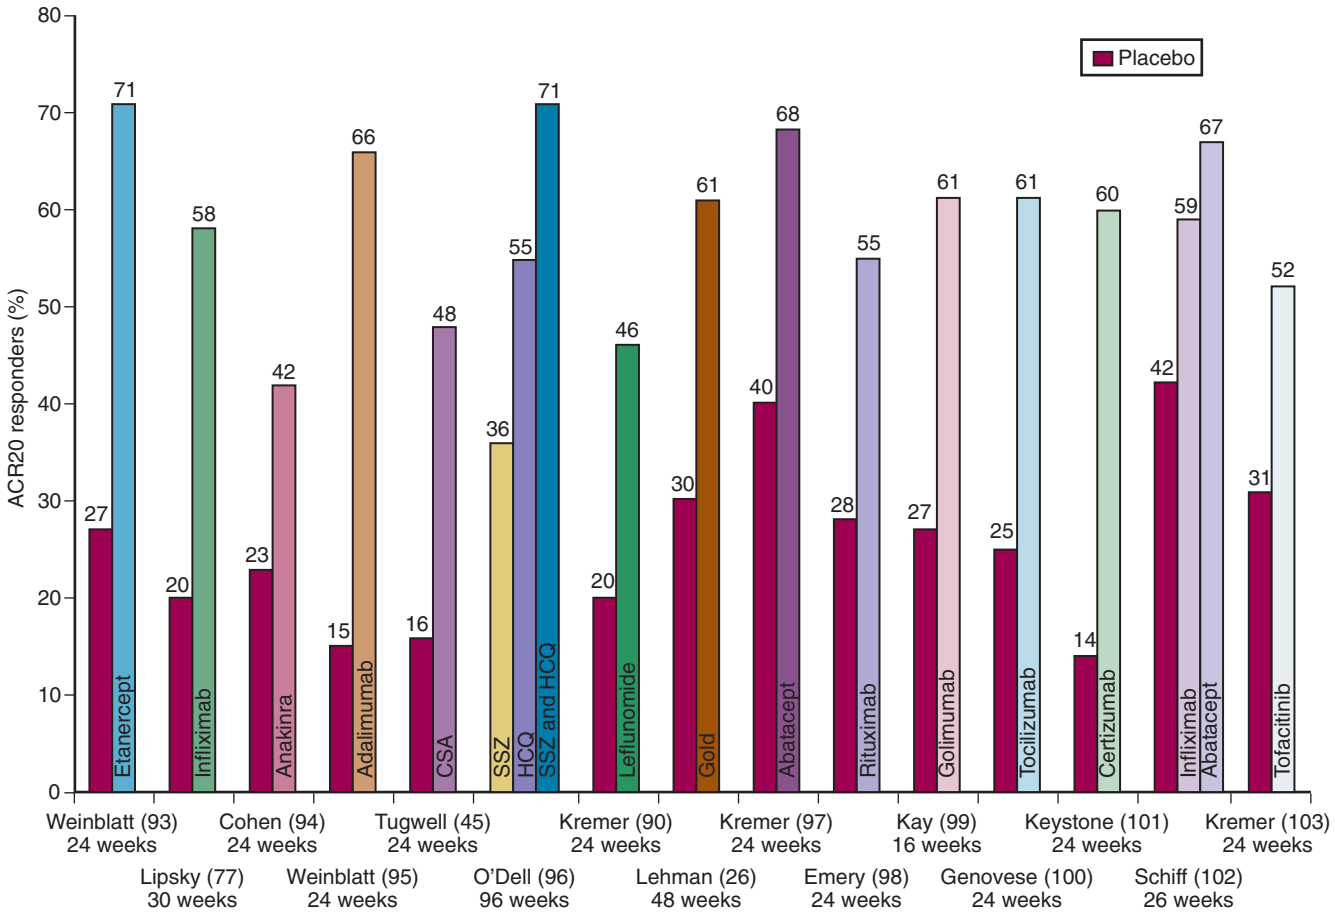

**Figure 71-2** Blinded trials of therapies in patients with active disease despite methotrexate. ACR20, American College of Rheumatology 20% composite improvement; CSA, cyclosporine; HCQ, hydroxychloroquine; SSZ, sulfasalazine.

to therapies is receiving attention.[54,55] Modification of the microbiome by tetracyclines is another possible mechanism of action. Tetracyclines also have the ability to inhibit biosynthesis and activity of matrix metalloproteinases, which have a principal role in degrading articular cartilage in persons with RA. This inhibition has been effective in osteoarthritis treatment. The presumed mechanism is through chelation of calcium and zinc molecules, which subsequently leads to altered molecular conformations of proenzymes sufficiently to inactive them.[56,57] Minocycline has mild but definite inhibitory effects on synovial T cell proliferation and cytokine production and has been shown to upregulate IL-10 production. Further evidence of its ability to modulate the immune system is the fact that it is known to induce anti-DNA antibody positive lupus in some patients, especially when it is used to treat acne.

Given in a dose of 100 mg twice daily, moderate statistically significant improvement in clinical parameters of disease activity was found in patients with established RA who were treated with minocycline compared with placebo.[58,59] Findings in the treatment of early-stage RA have been more impressive. In a study of 46 patients with early-stage rheumatoid factor (RF)-positive RA who had not received previous treatment, researchers reported that 65% of patients experienced 50% improvement in tender and swollen joints, duration of morning stiffness, and ESR (Paulus criteria), whereas only 13% of the placebo recipients improved similarly over a 6-month period.[60] In 2001, the results of a 2-year trial comparing minocycline with HCQ were published.[39] In this small study of patients with early-stage RF-positive RA, the patients treated with minocycline were more likely to achieve an ACR 50% composite improvement (ACR50; the primary endpoint) than were the patients treated with HCQ (60% vs. 33%) and were more likely to experience success in the tapering of glucocorticoids. This study reconfirms the potential utility of minocycline, particularly in early-stage RF-positive patients.

Although doxycycline is less frequently studied, evidence supports the use of this drug in the treatment of RA. In a trial of patients with early RA, doxycycline plus MTX was compared with the use of MTX alone. Investigators studied low-dose (20 mg twice a day) and high-dose (100 mg twice a day) doxycycline in combination with MTX and found that both approaches were superior to MTX alone.[61] It is intriguing to speculate that the doxycycline in this combination alters the gut microbiome to allow MTX to be more effective. Despite the positive results of this study, it needs to be replicated.

Potential adverse effects of tetracyclines include lightheadedness, vertigo, rare liver toxicity, drug-induced lupus, and, with longer-term use, cutaneous hyperpigmentation.[62] Elderly patients appear to be at an increased risk of vertigo. Lupus-like syndromes have developed in patients taking minocycline, complete with autoantibodies, including anti-DNA and occasionally perinuclear anti-neutrophil cytoplasmic antigen.[63] Drug-induced lupus has not been reported to develop with doxycycline or with the use of minocycline in patients with RA. The hyperpigmentation can be impressive and may limit treatment in some persons.[62] Hyperpigmentation resolves with discontinuation of minocycline and occurs much less commonly, if at all, with doxycycline.

### Nonsteroidal Anti-inflammatory Drugs

NSAIDs, including salicylates, which are covered in detail in Chapter 59, have been a ubiquitous part of RA treatment for more than a century. During the past several decades, as toxicities (particularly gastrointestinal,[64,65] cardiovascular,[66,67] and renal[68,69]) have become apparent and our DMARDs have become more effective, the use of NSAIDs, fortunately, has been declining. The somewhat surprising cardiovascular toxicities, which are now known to be strongly associated not only with the COX-2–specific NSAIDs but essentially with all NSAIDs, have been particularly concerning with regard to the RA patient populations in which the main excess mortality is largely due to accelerated cardiovascular disease. As with glucocorticoids, **NSAIDs should rarely be used without concomitant use of DMARDs**. Also as with glucocorticoids, the goal should be to taper use of NSAIDs as soon as possible to avoid gastrointestinal and cardiovascular toxicities.

## TREATMENT APPROACHES AND STRATEGIES

As previously detailed, the goal of treatment for all patients with RA is remission or at least low disease activity; other than toxicity concerns and, obviously, issues relating to expense, **clinicians should not focus on which drug or combination of drugs is used in an individual patient but should focus on getting patients to the disease activity target with whatever drugs achieve that goal.** There is no magic or correct DMARD or combination of DMARDs that is right for all patients. Each patient presents a unique challenge and comes with unique expectations, biases, disease activity level, damage burden, comorbidities, and, in many countries, insurance coverage issues. **One of the most important areas of investigation in RA is to identify parameters that will predict in a differential fashion which patient will respond to which therapy.** Thus far, no clear-cut answers that are applicable to the clinical care of the vast majority of patients have emerged.

Some investigators have suggested that treatment should be different for patients with RA who have good prognosis versus poor prognosis. This concept is problematic, because separating patients into those who have a good versus a poor prognosis is difficult. Although some data suggest that certain features are associated with worse prognosis (Table 71-6), unfortunately, no data exist that suggest that stratifying our therapies based on prognosis at the individual patient level yields better outcomes. An example might be that if we could perfectly score prognosis on a scale of 1 to 10, it would be conceivable that patients with intermediate scores would benefit the most from our most aggressive therapies, whereas patients with low scores do not need them and patients with the highest scores may have an unacceptable benefit-to-toxicity ratio. Most patients who meet the criteria for classification of RA in the clinic and essentially all those included in clinical trials have poor-prognosis RA, with several of the factors listed in Table 71-6. Regardless of the prognostic factors, the goal for each individual patient is to achieve at least a low level of disease activity. Until or unless parameters are identified,

rheumatologists will of necessity continue to use their clinical judgment at the individual patient level.

Without parameters that predict in a differential manner the response to medications in terms of efficacy or toxicity, one approach to treatment decisions is illustrated in Figure 71-3. Note that several "spins" of the wheel may be required. Figure 71-3 makes the point that we do not have these much-needed parameters. The figure also emphasizes that if we hope to treat RA in a rational, scientific way, it is critical that we find these parameters, and it highlights and reinforces the need to include biobanks with all of our clinical trials. With regard to individual patients, Figure 71-4 (ACR recommendations[3]) is perhaps a more practical approach. Specific patient populations will be discussed in the following sections.

## Treatment of the Disease-Modifying Anti-rheumatic Drug–Naïve Patient

The most critically important principle of treating RA effectively is to **initiate and rapidly advance DMARD therapy as early as possible in the disease process**. Although this principle is universally accepted, a paucity of rigorous data directly addresses this point. Few randomized, double-blind trials have been conducted in which patients are randomized to early-stage treatment versus late-stage treatment,[70-73] and it is very unlikely, not to mention unethical, that any more will be forthcoming. Rather, we accept this foundation principle based on the common and firm belief that treating patients early in the disease process prevents damage and deformity and preserves function. Many trials and case series provide strong, credible evidence to support this central tenet. Evidence to support this commonsense belief comes from cohort studies of early versus delayed therapy,[74] randomized studies of intensive therapy versus usual care,[7] RCTs of combination versus monotherapy,[8,22,36,75-79] and, finally, studies of what was previously defined as pre-clinical RA.[73]

One cohort study of note reported on patients who had recently received a diagnosis of RA. The first cohort received DMARD therapy early (a mean of 123 days after diagnosis), whereas the second cohort received DMARDs very early (a mean of 15 days after diagnosis[74]). The first cohort had significantly more radiographic damage at 2 years and, importantly, continued to have radiographic progression, unlike the second cohort. The findings of the TICORA trial (previously detailed[7]) clearly show the advantages of better control of disease with earlier treatment. Multiple studies in early-stage RA have demonstrated that when groups of patients are compared, those that receive combinations of therapy fare better than do those that receive monotherapy.[8,22,36,75-79] Some examples of these studies are COBRA, with the combination of MTX, SSZ, and prednisolone versus SSZ alone[36]; the Finnish Rheumatoid Arthritis Combination Therapy (FIN-RACo) trial,[75] with the combination of MTX, SSZ, HCQ, and prednisone versus SSZ; the BeSt study, with the multiple combinations compared with step-ups or switches[8,22]; the Anti-TNF Trial in Rheumatoid Arthritis with Concomitant Therapy (ATTRACT) trial,[77] with the combination of infliximab and MTX versus MTX alone; and the PREMIER study, with the combination of adalimumab and MTX versus each alone.[78] In all these trials and many others, the combinations outperformed monotherapy. However, as discussed in a subsequent section of this chapter, it does not follow that all patients need combination therapy initially.

The new ACR/EULAR RA classification criteria[1] should allow us to classify patients with RA earlier and therefore treat them earlier. The criteria, discussed in detail in Chapter 70, were designed to allow rheumatologists to classify patients in clinical trials with RA as early as possible. Gone is the previous absolute requirement that all patients must have certain features for a minimum of 6 weeks. The 6-week threshold still is acknowledged as important but is no longer required and many patients (perhaps most patients), particularly with poor prognostic features, will fulfill criteria before 6 weeks. Importantly, the presence of

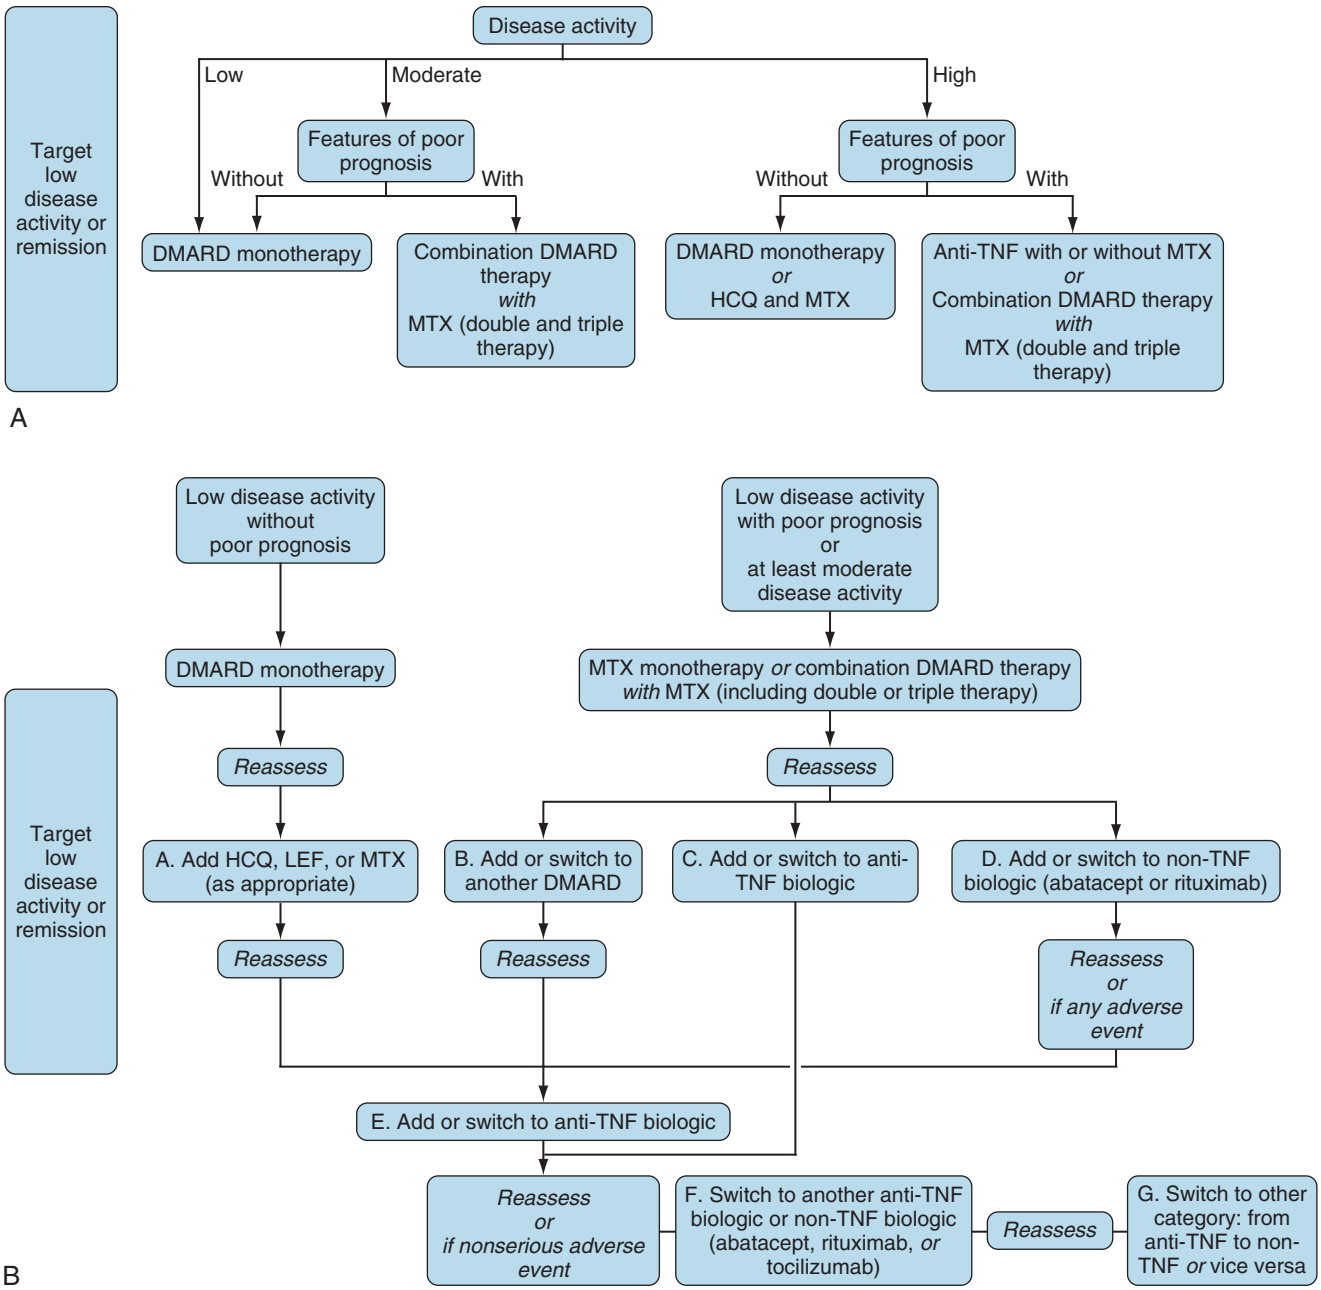

**Figure 71-4** American College of Rheumatology recommendations for treatment of rheumatoid arthritis.[2] **A,** Early disease. **B,** Established disease. DMARD, Disease-modifying anti-rheumatic drug; HCQ, hydroxychloroquine; LEF, leflunomide; MTX, methotrexate; TNF, tumor necrosis factor.

ACPA, particularly in a higher titer, is weighed heavily in the new criteria (3 points).

### Initial Therapy—The First Disease-Modifying Anti-rheumatic Drug

Upon accepting the premise that DMARD therapy should be started as early as possible, we must then ask which DMARD should be initiated and whether we should begin with monotherapy or combination DMARD therapies. Although many of the previously cited studies have shown that combinations outperform monotherapy in RCTs, this does not mean that initial combination therapy should be the standard approach for all patients in the clinic. Most clinicians initially start with DMARD monotherapy; the evidence to support this approach is discussed in a subsequent section of this chapter and is strongly validated by the TEAR trial[79] and the subanalysis of patients treated only with MTX from this trial.[80] The decision of which DMARD to initiate at the individual patient level is complex, and at this time it is clear that no one right answer exists for all patients and all clinical situations (Figures 71-3 and 71-4[2])**—one size, or in this case one drug, clearly does not fit all.** Many factors need to be considered, including but

not limited to, the patient's disease activity, comorbidities, and preference, the relative expense to the patient and to the health care system (weighing the benefits and including direct and indirect costs in our thinking), and importantly, where relevant, the desire of the patient (both female and male) to conceive. Until or unless parameters become available that allow selection based on data, this complicated decision will still require the clinician's best judgment.

Given all these factors, MTX should be the initial DMARD prescribed for the majority of patients. It is inexpensive (see Table 71-5), effective, well tolerated, improves survival rates,[81,82] and, importantly, is the cornerstone of most successful combination therapies (Figure 71-2). In particular, excellent data exist that anti-TNF therapy with all the currently available agents is much more effective with MTX on board both in terms of clinical and radiographic outcomes[78,83,84] (see Chapter 61 on MTX). MTX is usually administered orally at first, although subcutaneous (SC) dosing has more predictable bioavailability (Figure 71-5). In most cases, the dose should be pushed to 25 mg/week if necessary to control disease unless contraindications or tolerance problems exist. Most studies have shown that maximum efficacy may take up to 6 months to achieve but that in most situations, the response at 3 months predicts ultimate success. The bioavailability of oral MTX starts to plateau when doses of 15 to 20 mg are reached (Figure 71-5); therefore, if acceptable efficacy has not been achieved with a single weekly dose of MTX, two options exist. Splitting the weekly dose of MTX into two doses taken 4 to 12 hours apart on the day MTX is taken has been shown to improve efficacy, presumably because of better absorption.[85] If the patient is willing, the best strategy is to switch to SC MTX. MTX bioavailability and clinical response clearly improve if MTX is given in SC form compared with orally.[86,87] Some investigators have suggested that SC MTX, 25 mg/wk, be initiated in all patients, but this promising approach will require further study.[88] No data are available to compare split oral dosing to SC MTX. If MTX is optimally used, approximately 60% of patients will have a good response, and according to consistent data from several trials where MTX was only used at a maximum of 20 mg/wk orally, 30% will achieve low disease activity status[7,8,79,89] and will not require additional therapy.

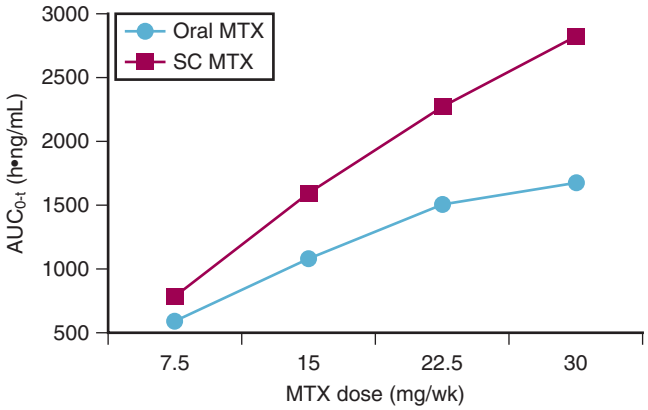

**Figure 71-5** Bioavailability of methotrexate (MTX): oral compared with subcutaneous (SC). AUC, Area under the curve.

### Initiating Treatment with a Single Disease-Modifying Anti-rheumatic Drug versus Combinations of Disease-Modifying Anti-rheumatic Drugs

Although most clinicians still favor starting treatment with monotherapy, combination DMARD therapy has clearly changed the treatment of RA forever. In the early 1990s, the treatment model called for individual DMARDs and then, when necessary, switching to a different DMARD. At that time, combinations of DMARDs were not used. Studies published in the mid-1990s showing the impressive efficacy and tolerability of various combinations of DMARDs dramatically changed the treatment paradigm.[6,48,75] Now the majority of patients with RA are treated with combinations of two, three, or more DMARDs. The first study that put combination DMARD therapy on the map was the so-called "triple therapy study" by the RAIN group of investigators.[6] This study clearly demonstrated that the triple combination of MTX, HCQ, and SSZ was significantly more effective than MTX alone or the combination of HCQ and SSZ. Importantly, this combination of DMARDs did not lead to an increase in toxicity. Multiple publications on other successful combinations of conventional DMARDs soon followed.[26,36,48,75,76,90]

Today the important question of whether treatment of all patients should start with combinations of DMARDs that are then stepped-down or whether monotherapy should be used initially and then stepped-up only if patients are not at target is an ongoing debate. Both approaches have their supporters, and data can be presented to support both sides of this question. On the one hand, there is no doubt that if short-term responses are examined in groups of patients, combinations outperform monotherapy. This outcome is true for combinations of conventional DMARDs,[36,75,76] as well as combinations of conventional DMARDs with use of a biologic agent.[78] On the other hand, the strategy of initial monotherapy with step-ups only in the patients who need it was clearly effective in the TICORA study (as previously discussed[7]) and, importantly, in the BeSt[8,22] and TEAR[79,80] trials (discussed in a subsequent section of this chapter), and although initial responses were better in both of the latter trials in the clinical parameters of patients initially treated with combination therapy, all groups in both the BeSt and TEAR trials had identical DAS or DAS28 scores at the end of 2 years. Clinicians do not treat groups of patients but individual patients, and if the results are similar at 2 years or beyond, **effective treatment approaches that minimize the number of DMARDs and therefore their potential toxicities and certain expenses will be desirable for patients and health care systems alike.**

## The BeSt Study

The BeSt study continues to be an important randomized, multicenter trial where 508 patients with early RA were randomized to receive one of four treatment "strategies" in an open-label study.[8,22,91] The four arms of the study were as follows:

- **Group 1:** Sequential DMARD monotherapy: initial MTX 15 mg/week → MTX 25 to 30 mg/week → SSZ → LEF → MTX + infliximab → etc.

- **Group 2:** Step-up combination therapy: initial MTX 15 mg/week → MTX 25 to 30 mg/week → MTX + SSZ → MTX + SSZ + HCQ → + MTX + SSZ + HCQ + prednisone → MTX + infliximab → etc.
- **Group 3:** Initial combination therapy: initial MTX 7.5 mg/week + SSZ 2000 mg/day + prednisone 60 mg/day (tapered to 7.5 mg/day by 7 weeks) → MTX 25 to 30 mg/week + SSZ + prednisone → MTX + CSA + prednisone → MTX + infliximab → etc.
- **Group 4:** Initial MTX and infliximab; initial MTX 25 to 30 mg/week + infliximab 3 mg/kg → infliximab 6 mg/kg every 8 weeks → infliximab 7.5 → infliximab 10 mg/kg every 8 weeks → etc.

Treatment adjustments were made every 3 months with the target of a DAS less than or equal to 2.4 (low disease activity). The DAS is calculated using the following four variables: Ritchie Articular Index (RAI; a count of 66 tender joints), Swollen Joint Count (SJC; 44 joints); the ESR (mm/hour); and the Global Health Assessment (GH) score (0-100): DAS = $0.53938 \times \sqrt{RAI} + 0.06465 \times (SJC) + 0.33 \times \ln(ESR) + 0.00722 \times (GH)$. The major results at 1 and 2 years are shown in Figure 71-6; both combination

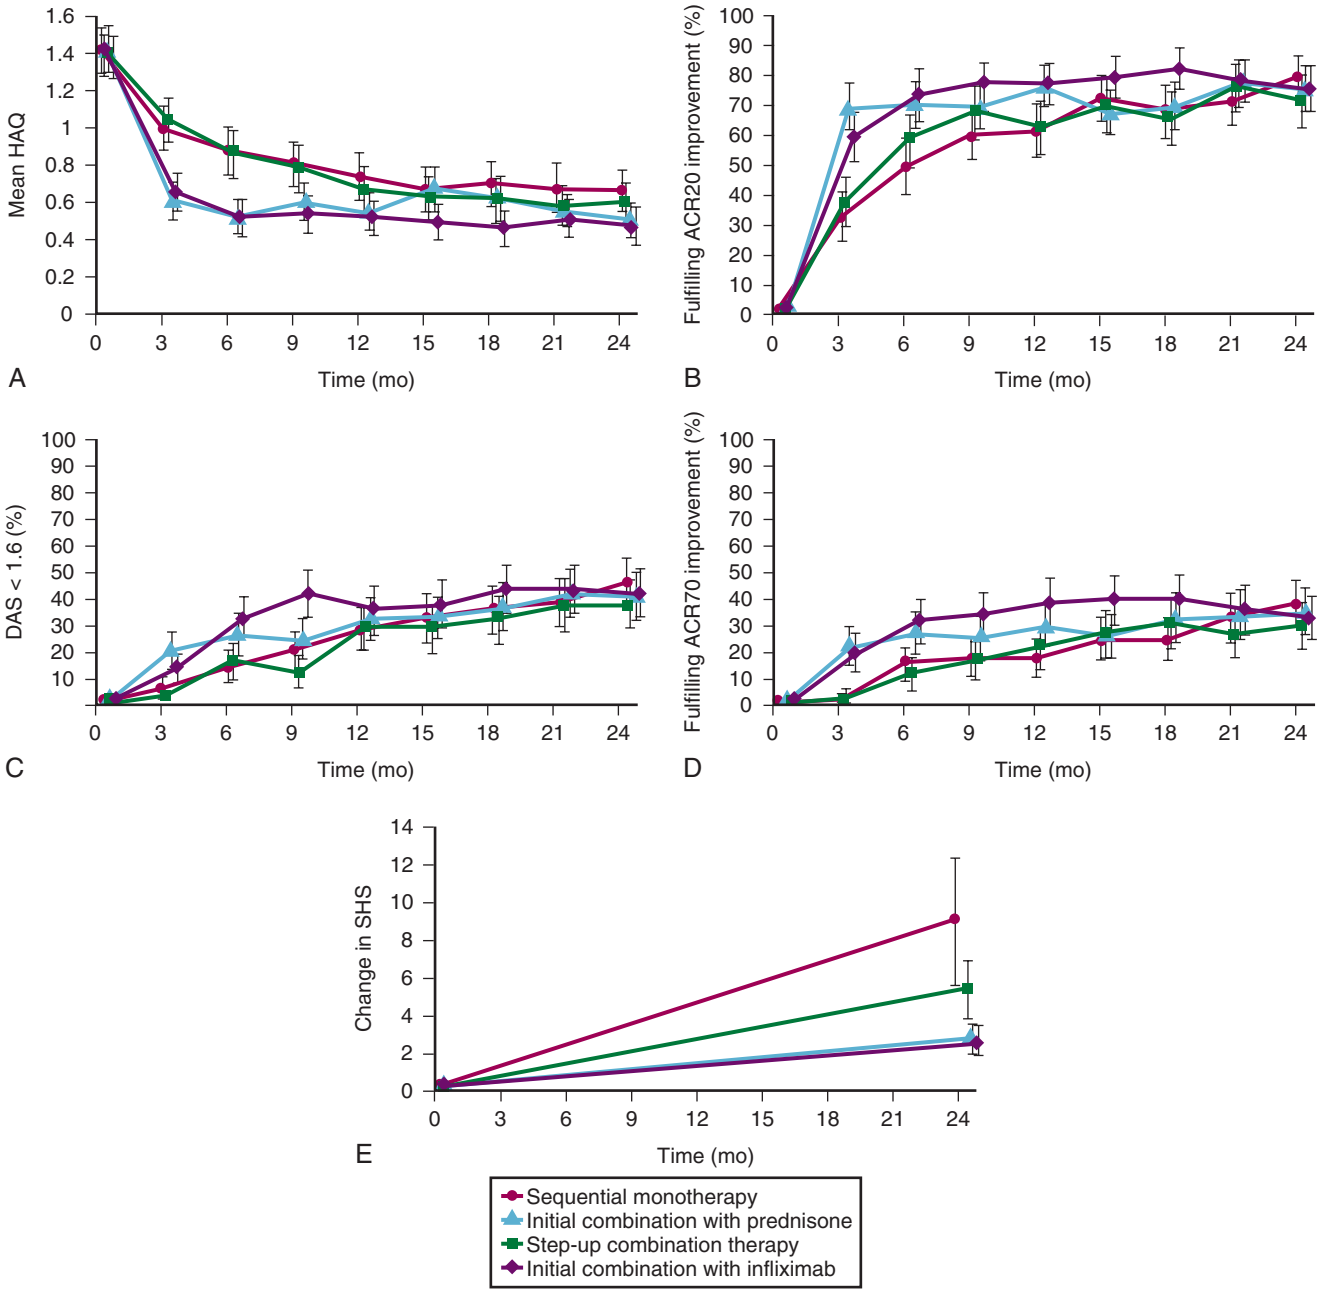

**Figure 71-6** Two-year results of the Dutch Behandel-Strategieen (BeSt) study. The error bars indicate 95% confidence intervals. ACR20, American College of Rheumatology 20% composite improvement; ACR70, American College of Rheumatology 70% composite improvement; DAS, Disease Activity Score; HAQ, Health Assessment Questionnaire; SHS, Sharp–van der Heijde score. *(Modified from Goekoop-Ruiterman YP, de Vries-Bouwstra JK, Allaart CF, et al: Comparison of treatment strategies in early rheumatoid arthritis: a randomized trial,* Ann Intern Med *146:406–415, 2007.)*

groups (groups 3 and 4) improved more quickly than did groups 1 and 2, which was expected, with high-dose prednisone in group 3 and a high initial dose of MTX and also infliximab in group 4. At 1 year, DAS and other clinical outcomes were similar in all four groups and, importantly, at 2 years they were identical. Health Assessment Questionnaire (HAQ) scores improved more in the early combination groups (groups 3 and 4) at 1 year but were not different at 2 years, and radiographic progression at 2 years was greater in group 1 than in group 2 and greater in groups 1 and 2 than in the combination groups (mean Sharp–van der Heijde score progression of 9, 5.2, 2.6, and 2.5, respectively). Progression of the joint space narrowing score (the importance of which is discussed in a subsequent section of htge text), although numerically higher in group 1, was not statistically different among the four groups (4.3, 2.1, 1.5, and 1.2, respectively). Interpretation of these differences is complicated by the fact that despite having disease for only 6 months, group 2 had more radiographic progression at baseline.

### Conclusions from the BeSt Study

One conclusion of the BeSt study is that all patients treated with a disease activity target will do well, even if they are receiving many different therapies. The type of therapy patients receive is not so important; it is only important that they are at low disease activity or in remission. Several important caveats must be noted:

1. The strategy of adding DMARDs, as in group 2, was more effective than the strategy of switching from one DMARD to another, at least for the DMARDs and their order of use in the BeSt trial. Although the clinical outcomes were similar at 2 years for these groups, radiographic progression was greater in group 1 (mean 9 vs. 5.2), more group 1 patients required infliximab (26% vs. 6%), and many group 1 patients ended up taking combinations of drugs anyway.
2. Initial therapy with combinations of conventional DMARDs (group 3) or combinations including biologic agents (group 4) work more quickly than step-up therapy (group 2). However, at 2 years, the clinical results were identical. There was a statistical advantage of the combination groups compared with the step-up group in terms of total radiographic progression (Δ2.5 points over 2 years); a difference was not noted in terms of joint space narrowing. This difference in radiographic progression is of no clinical significance unless it continues to grow at similar rates for years. Further strategies need to be used to further change therapies based on radiographic progress in the small group of patients (perhaps 10%) receiving only conventional therapy where it is relevant.
3. A subset of patients were able to discontinue drug therapy for a period. In the BeSt trial, if a DAS score of less than 1.6 was achieved for 6 months, patients were tapered off all medications; this scenario occurred in 115 patients (23%). Although many patients experienced a relapse, 59 patients (11.6%) were in remission during discontinuation of all treatment (median follow-up: 23 months[91]).

## Treatment of Early Aggressive Rheumatoid (TEAR) Trial

The TEAR trial was a landmark study of initial DMARD therapy in patients with early-stage (mean disease duration = 3.6 months), poor prognosis (all had RF- or ACPA-positive or erosive) RA.[79,80] It is the largest ($n$ = 755) investigator-initiated, randomized, double-blind trial in RA to date. TEAR was a 2-year study and sought to address two critical questions in this early-stage RA population:

1. Should treatment with combination therapy be initiated, or should patients be stepped-up to combinations of drugs only after a trial of MTX monotherapy?
2. Is combination therapy with MTX-ETAN superior to therapy with MTX-SSZ-HCQ (triple) therapy?

The 755 patients were randomized to the four groups, as illustrated in Figure 71-7. Randomization was performed in a 2:1 ratio, with twice as many patients randomized to the ETAN groups. Patients randomized to the MTX-only groups were stepped-up (72% of patients were stepped-up) to their assigned combination at 6 months in a blinded fashion unless their DAS28 scores were less than 3.2.

The major clinical findings are illustrated in Figure 71-8. All four groups had excellent improvement, with a mean ΔDAS28 of 2.8. For the primary endpoint of the study (mean DAS28 between weeks 48 and 102), all four groups were identical. Patients who were started on combination therapy (either triple or MTX-ETAN) had better results than did patients started on MTX alone at the 6-month point. However, this difference disappeared within 12 weeks of the step-up point, and the step-up group's DAS28 scores were identical to those of the other groups for the remainder of the study (Figure 71-8). Data of functional assessments and quality of life measures closely mirrored the DAS28 results. Radiographs were performed at initiation and at 48 and 102 weeks. Radiographic data are presented in Table 71-7, and the cumulative probability plot is shown in Figure 71-9. As shown, the radiographic outcomes of all four

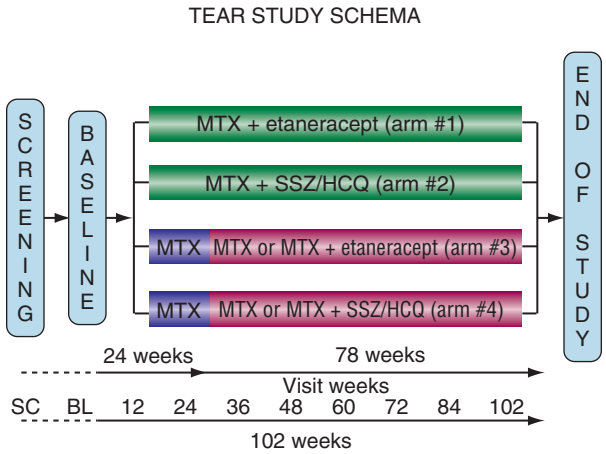

**Figure 71-7** Schematic of the four different treatment groups in the Treatment of Early Aggressive Rheumatoid (TEAR) trial.[71] Patients in arms 3 and 4 were treated with methotrexate (MTX) alone and step-up at 24 weeks if the Disease Activity Score in 28 joints (DAS28) was greater than 3.2. BL, Baseline; HCQ, hydroxychloroquine; SC, screening; SSZ, sulfasalazine.

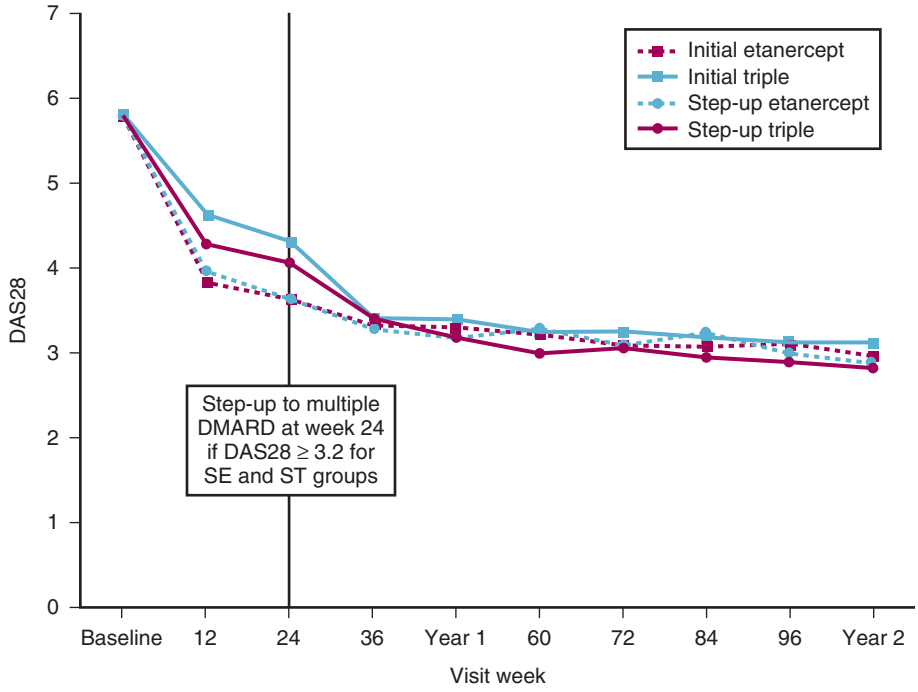

**Figure 71-8** Results of treatment in the four groups of the Treatment of Early Aggressive Rheumatoid (TEAR) trial over 102 weeks.[79] DAS28, Disease Activity Score in 28 joints; DMARD, disease-modifying anti-rheumatic drug; SE, step-up etanercept; ST, step-up Triple. *(Modified from Moreland L, O'Dell J, Paulus H, et al: A randomized comparative effectiveness study of oral triple therapy versus etanercept plus methotrexate in early, aggressive rheumatoid arthritis: the TEAR trial,* Arthritis Rheum *64:2824–2835, 2012.)*

**TABLE 71-7** Treatment of Early Aggressive Rheumatoid (TEAR) Radiographic Results

| Treatment Group | N | ΔTSS (over 2 yr) | SD |
|---|---|---|---|
| Immediate etanercept | 141 | 0.52 | 3.24 |
| Immediate triple therapy | 74 | 1.96* | 9.48 |
| Step-up etanercept | 139 | 0.76 | 2.75 |
| Step-up triple therapy | 63 | 1.36 | 5.00 |

*One outlier in this group had a ΔTSS of +78.5 points.
SD, Standard deviation; TSS, total Sharp score.

groups were superimposable. Table 71-7 shows that there was no difference between the four groups, but when all the ETAN groups are combined and compared with all the triple groups, the ETAN group had less total Sharp score (TSS) progression than did the triple group—ΔTSS of 0.51/year ($P = 0.047$). This small statistical difference was not clinically significant in the 2 years of the trial (see the following discussion about interpreting radiographic changes in clinical trials). Importantly, extensive data on adverse effects revealed no differences between the two groups. Many investigators had speculated that serious adverse advents may be more common in the ETAN-treated group, whereas minor toxicities such as gastrointestinal upset and others would be more common in the triple-treated patients; neither outcome was seen in this large, blinded, clinical trial. Analysis of the MTX-only group from the TEAR trial[80] reveals that the group that responded well to MTX initially continued to do well to the end of the trial (2 years), with the lowest DAS28 scores and radiographic progression of any group.

### Conclusions from the TEAR Trial

1. Strategies that initially treat patients with MTX and progress to step-up to combination therapy only if patients have not achieved their target at 6 months are as effective as initial combination therapy in disease control at 1 and 2 years, with no difference in clinical or radiographic outcomes. At the core of the debate about initial therapy—single DMARD versus combination—is the question of how soon is soon enough when considering control of RA? Is it important to control synovitis and radiographic progression in days or weeks, or is control by 3 to 6 months adequate? No clear long-term data exist to answer this important question. In both the TEAR trial and the BeSt study, as previously discussed, the groups treated with combination therapy early did better more quickly, but in both trials, the step-up groups looked identical to the early combination groups at 2 years in terms of clinical parameters. However, in both studies the early combination groups had very small but statistically significant less radiographic progression at 2 years. In the TEAR trial, this difference was 0.5 TSS/year, and in the BeSt trial, it was 1.3 per year.[22] Therefore central to this issue is the clinical relevance of small degrees of radiographic progression, which will be discussed in detail in a subsequent section of this chapter.
2. The strategy of using triple therapy was as effective as using the combination of MTX-ETAN. This observation is clearly important and should allow clinicians to be comfortable with this conventional therapy combination. Importantly, and somewhat sobering, the mean DAS28 scores of the four groups between 1 and 2 years

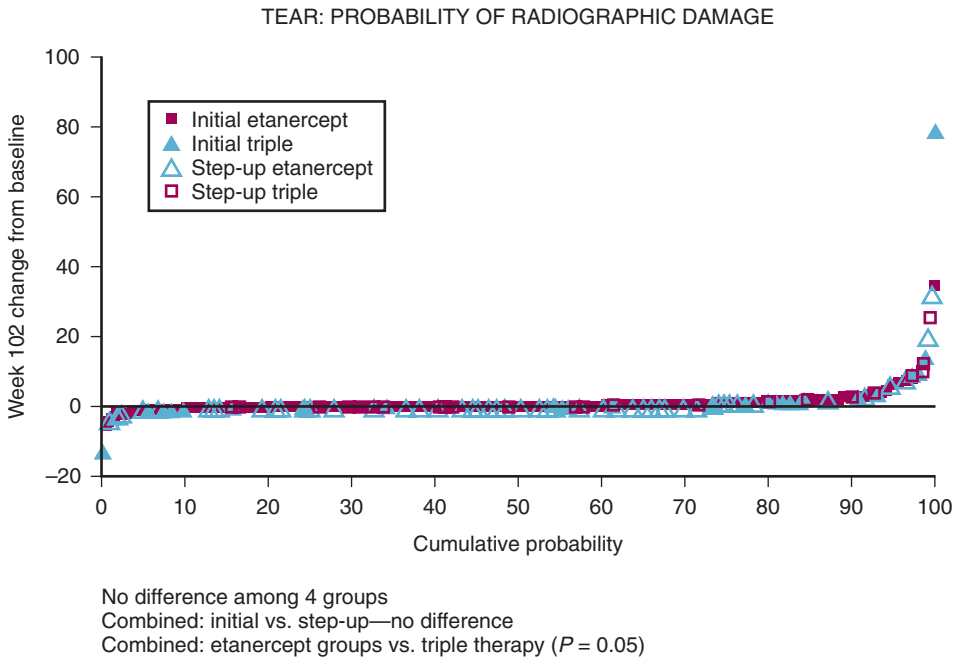

**Figure 71-9** Percentage of patients with radiographic improvement or progression during the 102 weeks of the Treatment of Early Aggressive Rheumatoid (TEAR) trial[79] by treatment group. Measured by total Sharp score.

of the trial was around 3.0, which means that almost half of the patients were not at target (DAS28 <3.2) regardless of treatment assignment. Therefore, in clinical situations, usually after 6 months of therapy, these patients should be switched to other therapies to obtain better control of their disease. For example, patients receiving triple therapy should be switched to or have ETAN added, or patients receiving MTX-ETAN should have HCQ and SSZ added. Trial data on patients who have failed to respond to triple therapy and are then treated with biologic agents or vice versa are discussed in a subsequent section, and both groups have the opportunity to do well.

## Treatment of Patients with Active Disease Despite Treatment with Methotrexate

As previously discussed, excellent data from clinical trials in which patients in general have high disease activity and poor prognostic features show that approximately 30% of patients will achieve a state of low disease activity or better if treated with modest doses of oral MTX. This figure is consistent across three major trials that documented this response.[8,22,79,89] If MTX therapy is optimized by switching to SC delivery and pushing doses to at least 25 mg/week, additional patients will experience disease control. Of the ~50% who have still not achieved this level of control, experience suggests that perhaps a third have improved significantly and that either the patient or the physician is not willing to escalate therapy. This still leaves approximately 40% of patients who will require treatment other than MTX monotherapy. The first question to ask is this: Should patients switch to another DMARD, or should other DMARDs be added to MTX**? Data from multiple sources, including the BeSt trial, as previously discussed, strongly support adding conventional DMARDs or biologic agents to MTX rather than switching to another DMARD.**[8,22,92] A recent trial has addressed the question of stopping MTX versus continuing MTX in patients with active disease who start taking ETAN. This trial randomized 151 patients to either stop taking MTX or continue to take MTX while starting ETAN. The group that continued to take MTX fared much better, with ACR20 scores of 86% versus 64%, and they experienced significantly less radiographic progression as well.[92]

Excellent data now exist that support the efficacy of 16 different clinically available DMARDs or DMARD combinations when added to MTX in this group of patients (i.e., those who have active disease despite treatment with MTX). This is true for all of the commonly used DMARDs, conventional and biologic agents alike. Figure 71-2 highlights the blinded clinical trials that have studied currently approved therapies in this patient population.[26,48,77,93-103] The problem for the clinician is the marked paucity of data with regard to comparing active therapies with each other in this critically important patient population. **Knowing that 16 different treatments are better than a placebo is of limited value because most clinicians do not commonly use placebos to treat patients.**

Two studies included in Figure 71-2 have provided some insight by comparing active therapies to each other in a limited way. In the study by the RAIN group, the combination of SSZ and HCQ appears to be better than either drug alone when added to MTX.[96] In the study by Schiff and colleagues,[102] abatacept was numerically better than infliximab for efficacy, but this difference did not reach statistical significance. This study has been faulted by some investigators because of the low and fixed dose of infliximab that was

used (3 mg/kg every 8 weeks). This criticism is fair with regard to the efficacy comparison, but importantly, even at this "low dose," serious and opportunistic infections were increased in the infliximab group compared with the abatacept group. A recent study in patients not receiving MTX has shown that tocilizumab is superior to adalimumab in terms of short-term efficacy, but this finding is applicable only to this limited population, because most patients should be taking MTX.[103] Fortunately, several recent studies have shed some additional light on patients with active disease despite treatment with MTX, as discussed in a subsequent section of this chapter.

**The really critical decision for clinicians is whether to add additional conventional therapies to MTX or take the leap and add biologic agents or tofacitinib.** Compared with the number of therapies that we know work in patients with active disease despite treatment with MTX, far less data address this question. The open-labeled Swefot study in this population of patients with active disease despite treatment with MTX compared adding SSZ and HCQ (triple) with adding infliximab.[89] At 6 months, both approaches appeared identical, with 25% of patients receiving triple therapy and 26% of patients receiving infliximab and MTX responding (EULAR good response); by 1 year, the results favored the biologic group (26% for triple therapy vs. 39% for infliximab), but this difference was no longer apparent at 2 years.[104] Importantly, in the 2-year data from this trial, there was no advantage to using the biologic agents first with regard to work disability.[105,106]

## Rheumatoid Arthritis: Comparison of Active Therapies Trial

Rheumatoid Arthritis: Comparison of Active Therapies (RACAT)[107] was a double-blind, randomized, controlled, noninferiority trial designed to answer the question, "Should conventional combination therapy be used before biologic agents in patients with active disease despite use of MTX?" RACAT was a multinational trial of 353 patients with RA who had active disease despite taking a mean of 19.6 mg per week of MTX. It was funded by the Veterans Administration, Canadian Institute of Health Research, and the National Institutes of Health. Of critical importance, this study was specifically designed to test the strategy of first adding conventional DMARDs (SSZ and HCQ) compared with first adding a biologic agent (ETAN) to MTX (Figure 71-10). Importantly, while maintaining the blinded condition, both groups were switched to the other treatment if they had not improved a clinically significant amount by 24 weeks. The primary endpoint was the improvement in DAS28 at 48 weeks (ΔDAS28) based on the original group randomization.

The strategy of first adding conventional DMARDs was not inferior to first adding ETAN (Figure 71-10A). Importantly, the switch rate from triple to ETAN was identical (27%) to the switch rate from ETAN to triple therapy (Figure 71-10B). This switch rate would have been nearly identical if the switch point had been ACR20 at 24 weeks (44% compared with 45%) instead of using the switch point of clinically significant improvement (ΔDAS28 >1.2). Further, no differences in radiographic outcomes were found, with the modified Sharp scores of the triple therapy group increasing by 0.54 compared with the ETAN group increase of 0.29 ($P$ = 0.43), and the radiographic cumulative probability curves were completely superimposable. Figure 71-10B also demonstrates the first data from a blinded trail on outcomes when patients are switched from triple therapy to ETAN and vice versa; the answer is that both groups improved clinically to a significant degree ($P$ = 0.001), and their amount of improvement is similar.

During the RACAT trial, more patients in the triple group experienced gastrointestinal adverse effects (30% vs. 22%; $P$ = 0.01), whereas more patients in the ETAN group had infections (37% vs. 25%, $P$ = 0.02). Serious infections occurred in 12 patients in the ETAN group and in 4 patients in the triple therapy group.

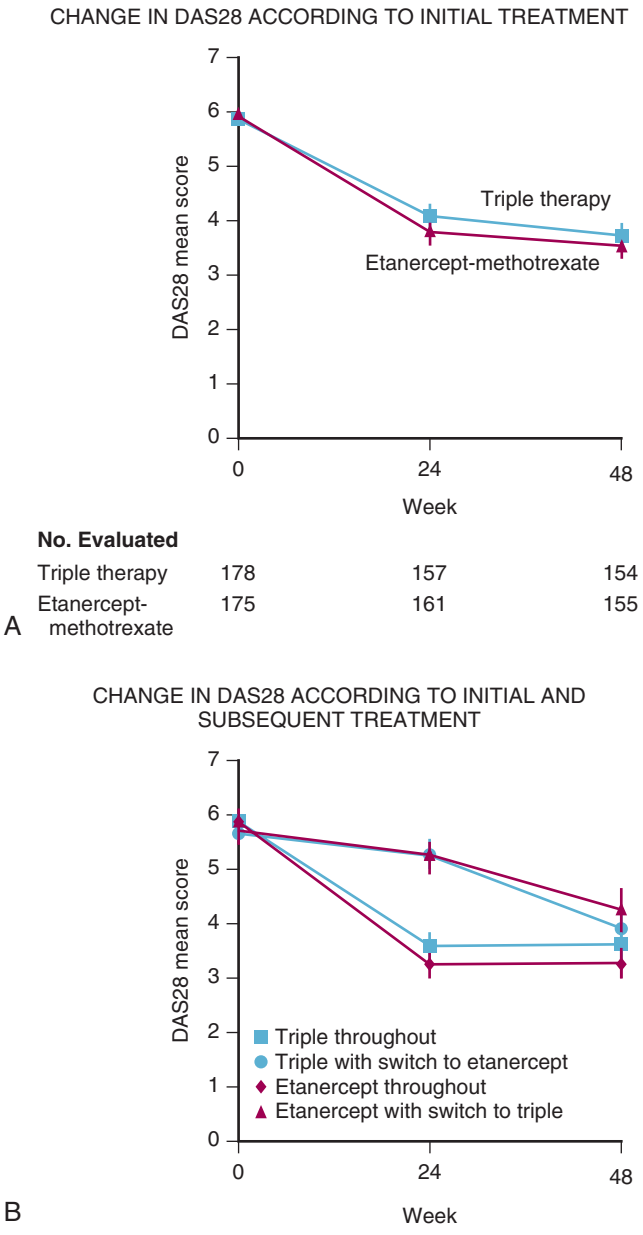

**Figure 71-10** **A,** Primary endpoint of the Rheumatoid Arthritis: Comparison of Active Therapies (RACAT) trial.[107] **B,** RACAT divided by switchers versus nonswitchers. DAS28, Disease Activity Score in 28 joints.

### Conclusions from the RACAT Trial

1. The strategy of first adding SSZA and HCQ to MTX (triple therapy) is not inferior to first adding ETAN clinically or radiographically.
2. Switching to ETAN in patients with active disease who are receiving triple therapy provides additional benefit, as does switching to triple therapy in patients with active disease despite taking MTX and ETAN.
3. Gastrointestinal toxicities were more common in the patients receiving triple therapy, and infections were more common in the patients taking ETAN.

Finally, the TEAR trial, as previously discussed,[79,80] addressed the question of conventional combination first versus biologic agent first indirectly, but importantly, in a double-blind study. Although the TEAR trial was designed to look at initial therapy, half of patients initially were treated with MTX alone and are relevant to this discussion. Of these patients treated with MTX alone, 72% or 271 patients did not achieve a DAS28 score of 3.2 or less and were treated with ETAN or the addition of HCQ/SSZ (triple therapy) in a blinded fashion. As shown in Figure 71-8, both of these groups looked identical 12 weeks after stepping-up therapy and continued to look identical as far as week 102, which was the end of the study. Importantly, with regard to radiographic progression, there was no difference in the radiographic progression of these MTX "failures" in the HCQ/SSZ group versus those in the ETAN group (mean progression of 1.7 vs. 1.1, $P = 0.57$).

Increasingly, demands are being made on rheumatologists to provide value-based care. This demand forces us to consider not only the clinical effectiveness of our therapies but also their economic costs and consciences. The longer term follow-up of the Swefot trial did not show benefit of the biologic arm compared with the triple arm, with fewer work days lost in the triple arm. Economic analysis of Swefot,[108] TEAR,[109] and RACAT[110] have all been presented at major international rheumatology meetings and have shown that the strategy of first using biologic agents rather than triple therapy in patients with active disease despite use of MTX costs approximately $1 to $2 million per quality-adjusted life-year gained.

Until further data are available that allow clinicians to select the best therapy for each patient in this group based on the different mechanisms of action (MOAs) of the many effective therapies (see Table 71-2), the aforementioned data dictate that conventional combinations should be tried first. When conventional combinations fail to help the patient achieve the disease activity target, data now show that TNF inhibition can provide additional benefit.[107] When a biologic agent is needed and until other data exist, largely because of their long track record, most clinicians favor a TNF inhibitor as the first biologic agent to use in this group of patients.

## Treatment of "Refractory" Patients or Those with Active Disease Despite TNF Inhibition

Despite the effectiveness of conventional DMARD combinations and the TNF inhibitors, a subset of patients will continue to have "unacceptable" levels of disease activity. Estimates of the size of this subset range from 10% to 40% of patients with RA. The lack of a universal definition of "refractory" and of "unacceptable" levels of disease activity hampers this discussion. With regard to levels of disease activity, it is clear and probably appropriate that clinicians are willing to tolerate more active disease in this "refractory" group before changing therapy, compared with patients who are naïve to treatment or those treated with active disease despite use of MTX only. Although clear data are needed, this approach currently seems prudent as the risk of toxicity and expense of treatment become significant factors.

Increasingly, as our expectations for our patients increase, we push to control disease sooner and use biologic agents earlier, and patients are being labeled "refractory" much earlier than ever before. When faced with a "refractory" patient, a close inspection of previous treatments that "failed" is in order. It is common for patients to be treated initially with low doses of MTX (≤15 mg by mouth) for 3 months and then be started on a TNF inhibitor with or without MTX, and then when they still have active disease after a few months, the patient inappropriately is labeled as "refractory." It is critical to assess whether MTX therapy has been optimized (see the previous discussion and Chapter 61); unless contraindications are present, most patients should have their dose of MTX pushed to 25 mg per week, and SC administration should be used. As previously discussed, data show that triple therapy is as effective as MTX-ETAN,[79,107] and thus this combination should be considered when resources are limited before progressing too far down the biologic agent road. Triple therapy can provide benefit in patients who have failed to respond to MTX and ETAN.[107]

For patients who truly are refractory to treatment, as with the previous section on patients with active disease despite the use of MTX, we urgently need markers or factors that inform us about the best of many possible approaches. The good news is that we still have multiple options with data to support them even in this difficult patient population, which include switching to another TNF agent,[111-114] starting rituximab,[115] starting abatacept,[116] starting tocilizumab,[117] or adding tofacitinab.[118] Currently, data directing this choice are limited (as discussed in the following text), and thus until markers or parameters are available, we will be making this decision largely empirically (Figure 71-3).

The strategy of TNF inhibition has been in use the longest, and because of its efficacy and the comfort level of clinicians with its use, many clinicians would switch to a second TNF inhibitor before switching to a biologic agent with a different MOA or to tofacitinib. A number of observational studies and one RCT support this approach.[111-114] From the observational studies, a consistent theme has been that if the first TNF inhibitor was discontinued for toxicity or loss of efficacy, patients have a better chance of efficacy with the second TNF than if the first was discontinued because of primary inefficacy (hazard ratio [HR], 2.7; confidence interval [CI], 2.1 to 3.4][111]). Discontinuation rates, particularly as measured in observational trials, are not the same as efficacy and reflect many things, including other treatment options that are available at the time of the study. In the previously cited study published in 2007,

golimumab, certolizumab, tocilizumab, and tofacitinib were not options.

A single randomized trial has addressed this question of switching to a second TNF inhibitor[114]; golimumab was administered after failure of at least one anti-TNF agent, and 43% of subjects responded, compared with 17% in the placebo-treated group. A special case in this patient population may be patients in whom antidrug antibodies have developed. Recently, data have been published with regard to antidrug antibodies in patients treated with adalimumab. After 3 years of treatment, antidrug antibodies developed in 28% of patients (secondary failures); in 67% of cases, these antidrug antibodies developed in the first 6 months.[119] Development of antidrug antibodies was associated with lack of or loss of efficacy (HR, 3.0; CI, 1.6 to 5.5), and patients were less likely to achieve remission (HR, 7.1; 95% CI, 2.1 to 23.4). Importantly, 38% of patients with antidrug antibodies compared with 14% of those without antidrug antibodies discontinued therapy because of lack of efficacy ($P = 0.001$). Perhaps of more concern was a recent finding that the development of antiadalimumab antibodies was associated with thromboembolic events (HR, 7.6; CI, 1.3 to 45.1; $P = 0.25$[120]). These interesting findings raise the possibility that **monitoring patients for development of antidrug antibodies, not only to adalimumab but also to other biologic agents, may be an important strategy to predict not only lack of efficacy but also to prevent toxicities such as thromboembolic events.**

Once the decision has been made to use a biologic agent with a different MOA, three choices are currently available (although the number of choices will likely increase in coming years): rituximab, abatacept, or tocilizumab. Few data are available to help differentiate among them. Based on strong suggestions in the literature that patients who are seronegative for ACPA and RF do not do as well compared with seropositive patients when treated with rituximab,[121,122] most clinicians would opt for either abatacept or tocilizumab in seronegative patients. Randomized trials have shown the efficacy of all three MOAs in this patient population.[115-117] These studies have been similar in design and also in the results of the intervention. Patients taking MTX who have active disease or intolerance to at least one TNF inhibitor have had the TNF inhibitor stopped and are randomized to receive the intervention + MTX or MTX + placebo. Response rates in the three different trials for ACR20 for the active drug versus placebo were as follows: rituximab, 51% versus 18%[115]; abatacept, 50% versus 20%[116]; and tocilizumab, 50% versus 10%.[117] All these responses, however, are less robust than in patients naïve to biologic agents. Based on the strikingly similar response rates of 50% across these three trials, there is little to choose from until further predictors of responses or comparison trial data are available. A limited number of trials have compared biologic agents to each other, but those trials were not in patients who had failed to respond to a TNF inhibitor. In the patients with active disease who were taking MTX and had baseline MTX, abatacept was similar to infliximab, with lower rates of serious infections.[102] In a head-to-head trial, abatacept and adalimumab were similar,[123] and in a monotherapy trial (ADACTA), tocilizumab was superior to adalimumab.[124] The later trial is of interest in patients who cannot take MTX. Some persons have raised concern about treatment with a second biologic agent after treatment with rituximab, which depresses B cell numbers significantly for at least 6 to 12 months. Limited data from observational studies provide some reassurance, because a significant increase in toxicities has not been reported.[125]

## The Niche for Tofacitinib and Potentially Other Janus Kinase Inhibitors

A paucity of data address what the therapeutic niche for tofacitinib should be. (See Chapter 65 for a detailed discussion on the tofacitinib and other JAK agents.) The efficacy of tofacitinib is not in question, but because cost and toxicity have not been major differentiating factors compared with biologic agents, its place in the treatment algorithm remains to be defined. Tofacitinib works well as monotherapy in early-stage disease[126] when added to MTX in patients who have active disease despite use of MTX[103] and in patients who have failed to respond to a TNF inhibitor.[118] One study has suggested that the efficacy of tofacitinib may be similar to that of adalimumab,[127] but other studies comparing tofacitinib and possibly other JAK inhibitors with distinct JAK isoform profiles with biologic agents and with conventional combinations are needed.

## How to Manage Patients in Remission Who Are Taking Disease-Modifying Anti-rheumatic Drugs

It is a powerful testament of how far therapy for patients with RA has come that this section on how to manage the patient in remission is included in this edition. It is now common practice for clinicians to ask how to taper DMARDs in patients who are "in remission." Indeed, a recent ACR expert panel acknowledged the importance of this question and included it as one of the top priorities for future investigation.[128] Putting aside the obvious difficulty in defining "remission," be it on clinical grounds, with radiographic evidence, or by using advanced imaging, clinicians see an increasing number of patients in "remission" or with very low levels of disease activity and are increasingly seeking direction regarding who should undergo tapering of what medications and when.

Unfortunately, again, few definitive data exist. We clearly do not have laboratory tests, inflammatory parameters, or cytokine profiles that can help predict which patients can safely undergo tapering of these agents. Studies that have examined discontinuation of all DMARDs have shown an unacceptably high rate of relapse.[22,129] Reports have suggested that seronegativity[130,131] and the absence of Doppler ultrasound–detected synovitis but not MRI synovitis[132] predict more successful tapering. Because of their well-chronicled toxicities, the highest priority should be discontinuation of glucocorticoids and NSAIDs for all patients. A number of trials[8,22,39] have shown that with effective DMARD therapy, glucocorticoid tapering not only is possible but should be expected. Perhaps the best example of this is from the BeSt trial, in which 92% of group 3 (the group that received high-dose prednisone initially) had stopped taking all prednisone at 2 years.[22] In this trial, prednisone was tapered only if the DAS was at or below 2.4 (a low level of disease activity).

Once the patient is no longer taking glucocorticoids and perhaps is taking only as-needed NSAIDs but is still in remission, it is more difficult to know which drug should be tapered next. A common situation is the patient who is undergoing combination therapy with MTX and a TNF inhibitor. Because of the expense and concerns for long-term toxicities, it would make sense to taper the TNF inhibitor to the lowest dose possible. Many of these patients in practice may have started taking this combination initially or had the TNF inhibitor added after receiving only a very short course of MTX. These patients may be similar to those in the TEAR trial who were started on the combination of MTX-ETAN.[79] For this group of patients, we can infer that ~30% of them did not need the ETAN and could have done extremely well with MTX alone, just as the 28% of patients who started taking MTX alone did not need a step-up in therapy. The MTX-only patients who did not step up not only had the lowest DAS28 score at 2 years (mean 2.7), but they also had the least amount of radiographic progression.[79,80] Unfortunately, unless we are talking about the small minority of seronegative patients,[130,131] we do not know how to select these patients.

If patients have been in remission for 6 months to a year and are being treated with a biologic agent, it seems prudent to decrease the dose or lengthen the interval between injections.[129-131] Although most biologic agents, certainly those administered subcutaneously, are dosed in a fixed, one-size-fits-all approach, we know from some of the earlier trials that doses that are lower than those usually clinically prescribed can be very effective. For example, the ERA trial compared doses of ETAN of 10 mg and 25 mg given twice weekly[133]; although the data were slightly better for the higher dose, the low dose clearly had substantial efficacy nearly equal to "full dose" ETAN, both as measured by clinical (ACR20) parameters and lack of radiographic progression. Therefore a significant percentage of patients may be overdosed, particularly those in remission. Our experience and that of others confirms that a slow and gradual lengthening of the interval between SC injections works well. In our clinic it is not uncommon for patients who are in remission to take 50 mg of ETAN every 2 to 4 weeks or 40 mg of adalimumab every 3 to 6 weeks. Conversely, a recent trial has shown that a fixed tapering schedule does not work.[129] In this trial, patients in remission while taking MTX and ETAN were then randomized to either a decrease in ETAN to 25 mg per week with MTX, taking MTX alone (i.e., use of ETAN was stopped), or taking no therapy. Predictably, the group that continued to take ETAN did best and the no-therapy group did the worst. Unfortunately, an unacceptable number (57%) of even the ETAN group were no longer in remission at 1 year.

Although wondering what to do with patients who are in remission while taking DMARDs is clearly a wonderful problem to have, further direction is certainly needed for this emerging group that fortunately is increasing in size. Trials to address this question with the collection of biomarkers will be increasingly important as patients continue to respond better with current therapies. It is clear that both ultrasound and MRI (discussed in the following text) can detect levels of synovitis that are not apparent on clinical examination. Ultrasound has shown promise in predicting which patients in clinical remission are most likely to experience flares while receiving stable therapy,[134,135] and synovitis on Doppler ultrasound predicts which patients more likely to experience flares when their medication is tapered. Even if, statistically, patients who are shown by ultrasound to have synovitis are more likely to have flares, the difference is of questionable clinical significance.[132] More importantly, ultrasound is not widely available, which significantly limits its practical application. Clearly, parameters that are clinically useful to differentiate patients who can successfully undergo tapering of medications are a high priority but largely remain to be elucidated.

### Use of Combinations of Biologic Agents

Combinations of conventional DMARDs and combinations of conventional DMARDs, especially MTX, with biologic agents have played a critical role in the vast improvement in responses to treatments that we currently see. However, thus far efforts to combine biologic products have not met with success. To date, studies to combine ETAN with anakinra have shown no improvement in disease control, with an ACR50 score of 41% in the ETAN-only arm compared with 31% in the combination arm, and they have shown an increase in serious infections in the combination arm (7.4% vs. 0%[136]). Similarly, in patients with active disease despite use of ETAN, patients were randomized to add abatacept or placebo; efficacy showed a nonstatistically significant trend toward improvement (ACR20 for combination, 48% vs. 31%; $P = 0.07$), but again, an increased risk of serious adverse events in the combination group (17% vs. 3%) and serious infections (4% vs. 0%[137]). Finally, a recent small trial in which patients who had active disease despite use of MTX and either ETAN or adalimumab were treated with the addition of rituximab or placebo showed very modest improvement in efficacy (an ACR20 score of 30% vs. 17%). Again, serious adverse events including infections were numerically greater in the group treated with combination therapy.[138]

Despite these less than encouraging results from early biologic combination trials, it is likely that ultimately patients will be treated with combinations of biologic agents. What is critically needed are good ways to measure the degree of immune suppression we create with our interventions—a thermostat for TNF, IL-1, or IL-6, if you will.[139] Currently, it is likely that suppression is inadequate in some patients, therefore not achieving optimal disease control, and that suppression in other patients is occurring at dangerous levels, leading to increased toxicity. When better immune system monitoring techniques are developed, not only will we be able to use the biologic agents we currently have in a more effective manner, but it is likely that we will be able to safely and effectively combine biologic agents to improve outcomes in terms of both efficacy and safety for patients.

## INTERPRETING RADIOGRAPHIC PROGRESSION AND THE USE OF OTHER IMAGING MODALITIES

What is the clinical relevance of radiographic progression? How much progression is significant, and over what period? Are erosions important, or should we be concerned only

with joint space narrowing? Finally, what role if any should ultrasound or MRI play in the management of RA?

In clinical trials, treatments of RA are evaluated by clinical parameters (e.g., ACR20 responses and DAS) and radiographic progression (TSS or van der Heijde Sharp [VHS]). This form of evaluation is problematic for a number of reasons. Clinical and radiographic progression is not always parallel. Perhaps the most dramatic example of this phenomenon from an RCT is the PREMIER trial, where, in the monotherapy arms, MTX alone was significantly better statistically than adalimumab alone, while at the same time, adalimumab alone was better than MTX alone with regard to radiographic progression (see Figure 71-11[78]). So which treatment was better? Some would say it is moot because the combination of the two outperformed either monotherapy arm in both measures. However, that misses the point about how to balance radiographic progression versus clinic parameters. Because **patients do not come to the clinic complaining of radiographic progression or demanding that it be stopped,** the question of how radiographic progression is related to factors that patients do care about—most importantly, physical function—is highly relevant.

Data exist that relate TSS or similarly total (VHS) progression to changes on HAQs (the gold standard for physical function in RA). These data suggest that a ΔTSS of 1 = a change in HAQ of ~0.01.[140] It is well accepted that a clinically significant ΔHAQ is ~0.22, so it follows that a ΔTSS of 22 is required for a radiographic change to be clinically relevant. This large Δ is never seen in clinical trials in which active therapies are compared. Thus, although many RCTs have shown statistically significant radiographic progression differences, no contemporary active comparator trials have shown clinically significant difference of any therapy versus any other therapy within the 1 to 2 years of the clinical trial. Additionally, recent data suggest that joint space narrowing correlates well with clinical progression but that erosions do not,[141,142] so perhaps we should not be concerned with TSS but only the joint space narrowing component. The next critically important point is as follows: Over what duration should we be concerned about radiographic progression? If a trial shows that therapy A results in two less TSS points progression per year compared with therapy B, then it follows that if those same therapies are used for 11 years, then patients receiving therapy A will have a clinically significant clinical benefit—HAQ 0.22 less than patients receiving therapy B. This is the magnitude of difference (ΔTSS of 1 to 2/year) that has been seen in trials and leads to claims of superiority of one therapy compared with another. Two problems are readily apparent with this type of extrapolation:

1. Within clinical trials, patients are often randomized to a therapy and continue to receive that therapy for the duration of the trial regardless of how they are doing. This approach does not reflect how patients are taken care of in the clinic; if patients are not doing well, therapy is or should be adjusted. Again, the PREMIER trial[78] is an excellent example of this issue; patients were in their assigned groups for 2 years (Figure 71-11B). Many patients were not having an optimal clinical response, and therapy would have been changed if this response had happened in a real-life clinical setting. These patients would not still be in the trial demonstrating their predictable radiographic progression, so in any RCT, radiographic progression that occurs after the time the therapy should have had maximal clinical benefit, and therefore patients would have been switched to a new therapy, is not clinically relevant. In the PREMIER trial, the therapies should have had maximal benefit by 6 months, so if the data after that time point include patients who were not at target (at least at low disease activity), then it is not relevant to patients seen in the clinic.
2. The second point is similar; to extrapolate forward in the example of a ΔTSS of two per year to 11 years of therapy

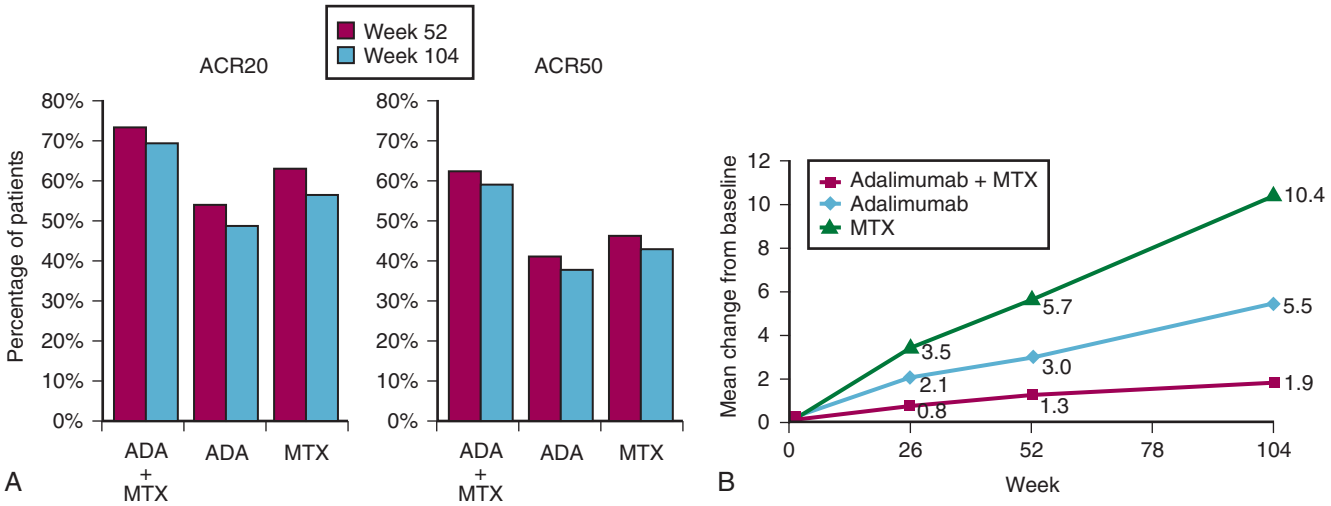

**Figure 71-11** Results from the PREMIER trial.[78] **A,** Clinical improvement measured by American College of Rheumatology (ACR) 20% and 50% composite improvement. **B,** Radiographic progression. ADA, Adalimumab; MTX, methotrexate. *(Modified from Breedveld FC, Weisman MH, Kavanaugh AF, et al: A multicenter, randomized, double-blind clinical trial of combination therapy with adalimumab plus methotrexate versus methotrexate alone or adalimumab alone in patients with early, aggressive rheumatoid arthritis who had not had previous methotrexate treatment,* Arthritis Rheum *54:26–37, 2006.)*

would only be relevant if all patients were doing well clinically. Patients who are not doing well clinically would have their therapies changed before the 2 TSS progressions per year had a chance to become clinically relevant.

Another major reason why radiographic progression is problematic for the clinician is that formal evaluation of radiographic progression is almost never performed outside of clinical trials; few patients have formal Sharp score assessment of radiographs. In this regard, routine yearly radiographs are not indicated in many patients with RA and only add to the expense of care. This is true for patients who are not doing well clinically, for those patients need a change of care regardless of what the radiographs show, and it is also true for patients who are unwilling or unable to change therapies. The small minority of patients who are at the clinical target but who are progressing radiographically are the ones for whom we hope to discover important information with serial radiographs.

Finally, the manner in which radiographic information is presented in clinical trials is problematic. Most commonly, the mean TSS progression of group A is compared with group B, statistical analysis is performed, and we are told that therapy A is superior to therapy B because one or two fewer TSS progressions occur in that group. A much more informative way to examine radiographic outcomes is to look at cumulative probability plots for radiographic changes (Figure 71-12) for the Trial of Etanercept and Methotrexate with Radiographic Patient Outcomes (TEMPO) trial[83,84] and Figure 71-9 for the TEAR trial.[79] When data are looked at this way, it is readily appreciated that a small number of patients, perhaps 15% to 20% in the TEMPO trial and even fewer in many studies, are driving the radiographic outcome. In the TEAR trial, there are no differences across the four groups in the probability plot. **With this epiphany, we must ask the following important questions: Who are these patients, and how do we focus on this small group that would benefit from a different therapy and not subject the other 80% to 95% to additional risks and expense?** Recently, as previously mentioned, Aletaha and colleagues[141] have called into question the relevance of erosions with regard to clinical correlations and have suggested that joint space narrowing correlates much more strongly with clinical progression; therefore, going forward, we need to ensure that we take this factor into account.

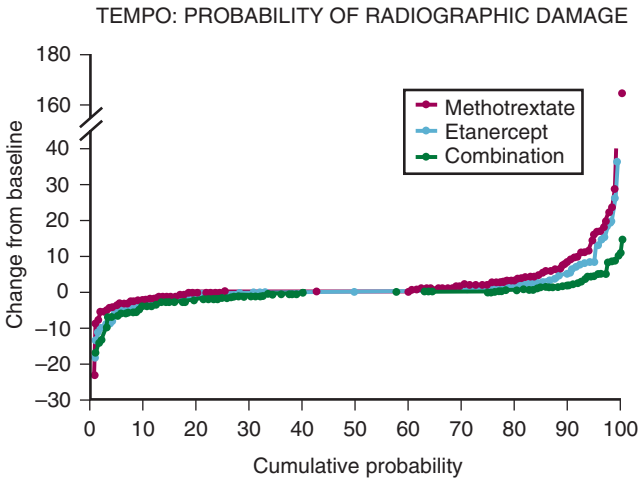

**Figure 71-12** Radiographic probability of progression plot from the Trial of Etanercept and Methotrexate with Radiographic Patient Outcomes (TEMPO).[72,73]

Finally, what is the place, if any, of "advanced" imaging techniques in evaluating patients with RA? Clearly, both ultrasound and MRI are powerful techniques to evaluate early erosions and to detect synovitis. One potential use of these obviously sensitive techniques, as previously suggested, may be to verify the true absence of synovitis in patients who are believed to be in remission on clinical grounds.[134] Until further research is available, these techniques will remain largely research tools with regard to routine care of patients with RA.

## ADJUNCTS TO MEDICATIONS

### Patient Education

RA is a lifelong disease, so it not only makes sense that patients who are educated about their disease do better, but good data exist to show that education leads to better outcomes.[143] Use of the Arthritis Self-Management Program has been shown to lead to less pain, decreased visits to physicians, and economic savings.[144,145] Chronic diseases such as RA affect the entire family, and participation of spouses in educational group sessions leads to additional beneficial effects.[146] Training in stress management is particularly effective in improving measures of helplessness, coping, pain, self-efficacy, and health status.[147] Unfortunately, formal education level, a factor that we cannot modify, is associated with morbidity and mortality rates. Formal educational level is inversely proportional to these outcomes, and this finding cannot be explained by age, duration of disease, joint count, functional measures, or medications.[148]

It is clearly important for patients to take an active role in the management of their chronic disease. The more patients understand their disease and medications, the more control they feel they have over the entire situation. The bond that develops between the patient and physician as they work together to control this lifelong disease is an important factor in outcome and the satisfaction level of both parties. The stronger the bond, the less likely patients will become frustrated and turn to alternative therapies that are not only expensive but may do more harm than good.

### Pain Control

If patients with RA are treated early and effectively with DMARDs and therapy is escalated to achieve excellent control of the active components of disease, the need for specific pain medications, particularly narcotics, can be minimized. If pain is a major problem, the first thing to do is review the DMARD program and modify it to achieve maximum control of any active synovitis. Unfortunately, some patients present later in the course of their disease after substantial joint damage has already occurred, and their pain will need to be addressed. Pain can be the

factor that limits effectiveness of physical and occupational therapy, and as pointed out during a special workshop sponsored by the National Advisory Board for Arthritis and Musculoskeletal and Skin Diseases, it is frequently undertreated in patients with arthritis.[149] In addition to inhibiting function, pain is a major cause of depression in patients with polyarthritis. To maximize therapy in patients with early-stage RA or undifferentiated polyarthritis, pain must be controlled without altering consciousness or generating addiction. Treatment strategies favoring education, rest, exercise, and disease-modifying therapies generally are favored as an approach to pain control in persons with arthritis, and strategies that rely on narcotic derivatives may not address control of active RA. In most medical centers, experts in pain management are available for consultation by rheumatologists and primary care physicians (PCPs). Chapter 67 provides an excellent discussion of analgesics in rheumatic disease.

### Rest and/or Exercise and Activities of Daily Living

Education and supervision of a patient by trained professionals regarding the importance of finding the best balance of rest and exercise for inflamed joints is essential. This component of therapy can be started well before a definitive diagnosis is made. No matter the cause, finding this balance should ensure that a patient develops or retains sufficient strength to support joint function without exacerbating inflammation.

Details of physical and occupational therapy are outlined in Chapter 38. A patient with acutely and severely inflamed joints may not be the ideal exercise candidate and may need application of resting splints to immobilize the joint until anti-inflammatory medications, specifically DMARDs, take effect. Even the most painful joints, when splinted, must be moved passively through a full range of motion each day to prevent flexion contractures, particularly in children. For moderately inflamed joints, isometric exercises with muscles contracted in a fixed position (the resting length of the muscle) provide adequate muscle tone without exacerbating joint inflammation and pain. Maximal contractions, held for 6 seconds and repeated 5 to 10 times, performed several times each day, can prevent further loss of muscle mass around arthritic joints.

Patients with well-controlled arthritis will benefit from variable-resistance programs or high-intensity strength training, which has been shown to provide significant improvements in strength, pain, and fatigue levels. Older patients with RA benefit from progressive resistance exercises, similar to younger patients. In a study of older patients given closely regulated workouts on pneumatic resistance equipment, maximal strength of all major exercised muscle groups was increased 75% without exacerbation of clinical disease activity.[150] Not only does prescribed sustained exercise increase muscle strength, but also it helps the ability of patients to perform daily routines, improves global assessments and moods, and can decrease pain.[151]

Most patients with RA should have one or more sessions with a licensed occupational therapist (OT) to learn how to preserve joint function and alignment while carrying out the necessary and enjoyable activities of daily living and to be introduced to the assistive devices that are available. The basic concept is to avoid excessive force applied across non–weight-bearing joints and to avoid unnecessary impact loading on weight-bearing joints. A prospective and controlled Canadian trial demonstrated that home therapy by OTs produced a statistically significant and clinically important improvement in function in patients with RA.[152]

## TREATMENT OF RHEUMATOID ARTHRITIS COMORBIDITIES AND THE INTERACTIONS OF RHEUMATOLOGISTS WITH PRIMARY CARE PHYSICIANS

The best possible outcomes for patients with RA can be achieved only with a carefully orchestrated collaboration between PCPs and rheumatologists. On the one hand, the ever-increasing complexity of RA management options, combination therapies, and possible toxicities of therapy have made it increasingly essential that all patients with RA be treated by rheumatologists. Good-quality evidence shows that patients with RA are more likely to be taking DMARDs, as well as combination DMARDs, and are happier with their care when they are treated by rheumatologists.[153-155] On the other hand, the realization of the critical nature of the comorbidities associated with RA, especially cardiovascular disease, make ongoing engagement of a PCP essential[156] to produce optimal outcomes.

A significant amount of data demonstrate that patients with RA have better outcomes when rheumatologists are the primary manager of the RA. In one series of 561 patients with definite RA who were followed up for 20 years, the patients treated by a rheumatologist during the first 2 years of their disease fared significantly better than did the patients who were not treated by a rheumatologist during this period.[157] The favorable outcome could be related to an early start of DMARD therapy. Further, data indicate that regular ongoing care by a rheumatologist (a mean of 8.6 visits per year) results in less functional disability than that found in patients who received only intermittent, sporadic care by a rheumatologist.[158] Analysis of these data supported the interpretation that worsening disability was not the reason for intermittent care but rather a consequence of it. Additionally, evidence supporting care by a rheumatologist showed that patients who had access to a rheumatologist had higher performance scores than did patients who were treated only by a PCP. Access to specialist care resulted in significant improvements in arthritis care, comorbid illness, and health care maintenance overall beyond being treated by a PCP alone.[159]

Despite the importance of the rheumatologist, the PCP needs to be closely engaged (Table 71-8). Recently, the comorbidities of RA have been highlighted and include premature atherosclerosis and congestive heart failure and increased risks of osteoporosis, fractures, and infections. A recent review by a panel of cardiologists and rheumatologists highlighted RA as a significant risk factor for cardiovascular morbidity and mortality on par with diabetes.[160] In this regard, the PCP needs to aggressively address traditional cardiovascular risk factors such as hypertension and especially hyperlipidemia in patients with RA. Statins should be used aggressively because the primary reason for

**TABLE 71-8** Role of Primary Care Physicians in Treating Rheumatoid Arthritis

| |
|---|
| Monitor and aggressively treat cardiovascular risk factors |
| Monitor and treat/prevent osteoporosis* |
| Recognize toxicities of RA medications and initiate appropriate and timely workup* |
| Recognize the risks for infections and ensure immunization status is current |

*In partnership with a rheumatologist.
RA, Rheumatoid arthritis.

the excess mortality seen in persons with RA is cardiovascular. As an added bonus, statins, probably as a result of their anti-inflammatory effects, have been shown in animal studies of RA models[161] and in a least one RCT in humans[162] to decrease RA activity. Further, data show that statin use may protect against the development of RA.[163]

Because RA and particularly glucocorticoids are risk factors for osteoporosis, the PCP, in concert with the rheumatologist, need to address this issue. Most patients should be receiving calcium and adequate vitamin $D_3$. Bisphosphonates have been shown to prevent steroid-induced osteoporosis,[164] and their use should be strongly considered in patients taking steroids on a long-term basis unless contraindications exist (e.g., women of childbearing age).

With the increased risk of infections experienced by patients with RA because of their disease and therapies, up-to-date immunizations, including yearly influenza shots, every-5-year pneumococcal vaccinations, and appropriate zoster vaccinations, are critical.[2] The latter is a live-virus vaccination and should be avoided in patients currently receiving biologic agents. Current recommendations are to give the zoster vaccination 2 weeks before starting any of the biologic agents. Influenza and pneumococcal vaccinations can be safely given to patients who are taking biologic agents with reasonable immunologic response[165] except in patients taking rituximab, for whom response is severely impaired.[166,167] The rheumatologist and PCP should push hard for smoking cessation for all the usual reasons plus concern for cardiovascular and pulmonary disease that is already over represented in RA; cessation has the added benefit of potentially making patients more responsive to therapies.[168] Finally, because the PCP often sees the patient first during an illness, the PCP needs to be familiar with the common toxicities of RA medications, including concerns about MTX in the patient with decreasing renal function, MTX pneumonitis, and the need for heightened concern and aggressive workup of all potential infections, including opportunistic infections in immunosuppressed patients, particularly those taking biologic agents. Often the difference between life and death or at least between excellent outcomes and less than optimal results is the rapidity of response to the early warning signs for conditions as simple as cellulitis or a pulmonary infiltrate.

Clearly the best care is achieved when a team of a rheumatologist, a PCP, and an educated patient all work closely together. Timely consultation with physical and occupational therapists and orthopedic surgeons also plays a role in optimal outcomes for patients with RA. Although the need for joint replacement surgery is thankfully decreasing, few interventions have been as successful in improving patient mobility and quality of life as having properly timed hip and knee replacements. With the potential of huge changes in health care delivery on the horizon, at least in the United States, it may be an increasing challenge to ensure that the right team is always engaged to achieve the best outcomes for each patient.

## EVIDENCE THAT PATIENTS WITH RHEUMATOID ARTHRITIS ARE DOING BETTER

The prognosis for patients with RA has improved dramatically. Every rheumatologist who has been fortunate enough to see the changes during the past quarter of a century is only too happy to witness the improvements in care. The clinic days when wheelchairs were commonplace and symptomatic C1 cervical subluxations, chronic leg ulcers, constrictive pericarditis, and corneal melts were not uncommon in patients with RA are, we hope, gone forever. Despite this firmly held perception by clinicians, strong data to support this change have been slow to accumulate.

Recent data from Olmstead County shows that patients with RA diagnosed after 1995 lived significantly longer—almost 9 years longer—than did those diagnosed prior to 1995.[169] In the same cohort of patients in Olmstead County, knee surgery decreased by 46% and hand surgery decreased by 55%.[170] Data from more than 35,000 U.S. veterans with RA showed greater than a 30% reduction in extra-articular manifestations of RA since the year 2000.[171] Ward,[172] using data from California for the years 1983-2001, showed that hospitalizations for RA vasculitis or splenectomy for Felty's syndrome decreased by 33% and 71%, respectively.[172] Further, primary knee arthroplasty for RA decreased by 10%. Early unpublished reports from many centers indicate that joint replacement surgery for RA many be reduced by as much as 50% to 80%. Data from Sweden and Spain[173] both show that disease activity scores and health assessment scores have significantly improved during the past decade.

Investigators postulate that it may take up to 20 years for the results of a change in therapy or approach to fully translate into improvement in long-term outcomes, such as joint replacements and mortality. The aforementioned encouraging data likely reflect our therapies of the early to mid-1990s and, therefore, we expect that these early reports are the leading wave of good news as some of the therapeutic principles in use for the past decade begin to show their full affect.

## RESEARCH AGENDA: UNMET NEEDS

As mentioned numerous times in this chapter, huge gaps remain in our knowledge of how to best utilize the 20 clinically available DMARDs (see Table 71-2) into optimal care for each patient with RA. At the top of the list of important clinical questions is the urgent need for factors or parameters that would allow us to differentiate the probability of response to or toxicity from different DMARDs at the level of individual patients. This information is important for selection of DMARDs for all the categories of patients previously discussed—those who are DMARD naïve, patients with active disease despite taking MTX, and patients who

have not responded to MTX plus a TNF inhibitor. Several studies have suggested that factors such as serologic status,[174] human leukocyte antigen-DRB1 haplotypes,[175] and a variety of findings in synovial tissue[176-178] are statistically associated with responses to therapy, particularly to TNF inhibition. Unfortunately, none of these differences approaches clinical significance. With regard to specific trials needed in each of these patient groups, a recent ACR task force was formed to prioritize the clinical research trials needed to most expeditiously advance the knowledge base needed to move RA treatment forward.[128] After making the strong recommendation that all further trials include biologic samples to aid in our search for factors that differentiate therapeutic responses, they ordered the trial priorities as follows:

- Trials to elucidate the possible role of induction therapy in early disease
- Treatment of active disease despite use of MTX and the first TNF inhibitor
- Tapering therapy for patients in remission
- Treatment of active disease despite use of MTX
- Stratifying patients to determine in advance the most appropriate therapy in order to move beyond the current trial-and-error approach

Except for studies in patients in remission, the task force emphasized the need for trials that compare active therapies to each other. Further trials that demonstrate the superiority of product X over placebo in any of the aforementioned areas where multiple treatments have already been shown to work will not provide useful information to clinicians trying to make important clinical decisions. True comparative effectiveness research is needed to address the multiple options available for patients with RA in all of the previously listed categories. Further, the task force stressed the importance of innovative trial designs that more closely mirror clinical practice.[128] Examples include trials that allow escalation or switching of therapies in a blinded fashion based on clinical response and not allowing patients with ongoing active disease to continue to be treated with fixed therapies after the point of maximal response.

## THE HORIZON

It is always difficult to predict the future, particularly in an area of rapid change such as RA. Certainly, the authors of the early editions of this book could not have predicted the giant strides that have been made in RA treatment. Despite the progress that has been made, no cure exists for RA, and the vast majority of our patients require lifelong DMARD therapy, and thus plenty of opportunity remains for further progress. As Bill Gates remarked, "We always overestimate the change that will occur in the next two years and underestimate the change that will occur in the next ten." By the time the 11th edition of this book is published, we will almost certainly have several new biologic agents and perhaps several new small-molecule DMARDs available for use in treatment regimens. Regardless of new therapies that expand our portfolio of choices, the two areas where we still need to see the most progress are profiling patients based on parameters that predict differential responses to different therapies and monitoring the types and intensity of immunologic modification that we are producing. If substantial progress can be made in these areas, even without new therapies, we should be able to obtain vastly superior and more expeditious disease control.

On a somewhat more pragmatic note, the treatment of RA has become an expensive endeavor, and with all the changes in health care and the continuing increases in its cost, it is imperative that we have appropriate studies that allow us to provide the best value-based care to patients. If we do not have the appropriate research to justify expensive medications, we will have increasing difficulties justifying their use. Therefore it is critical that trials be designed with this factor in mind and that long-term costs, both direct and indirect, of suboptimally controlled RA be part of the equation.

Many observations clearly show that the immune response that becomes RA starts years[179-181] before most patients present with the classic symptom complex. Studies to elucidate this transition are under way,[182] and studies to treat presymptomatic RA are not far behind. Even further, these studies on pre-clinical disease hold the promise of elucidating the triggers of RA and, if so, the ultimate goal of RA prevention cannot be far behind.

CHAPTER 72

# Early Synovitis and Early Undifferentiated Arthritis

Annette H.M. Van Der Helm-Van Mil • Thomas W.J. Huizinga

**KEY POINTS**

- ***Early synovitis*** **refers to synovitis that is detected by physical examination; the symptom duration defined by *early* has changed with time.**
- **Intervention in inflammatory arthritis with symptoms less than 12 weeks can potentially prevent damage later.**
- **Undifferentiated arthritis (UA) is a diagnosis of exclusion. The phenotypic characteristics and outcome depend on the classification criteria used.**
- **Few clinical trials have been performed in UA, and treatment strategies were not adjusted to an individual patients' chance of spontaneous remission versus progression to rheumatoid arthritis.**

## WHAT IS EARLY-STAGE SYNOVITIS?

Recent data suggest that early therapy and achieving low disease activity improve long-term outcomes in inflammatory arthritis.[1,2,3] These observations have increased awareness among rheumatologists of the importance of early diagnosis and treatment. As a result, considerable pathophysiologic research and clinical trials have focused on identifying early-stage synovitis as soon as possible. Stratifying patients into well-characterized diseases, such as rheumatoid arthritis (RA), is essential so that appropriate therapy can be initiated. Equally important, identifying patients with a high chance for spontaneous remission is needed to avoid overtreating individuals with transient undifferentiated synovitis.

Uniform descriptions of patients and accurate diagnostic criteria for early-stage synovitis are essential for proper interpretation of clinical research. At present, no standardized definition for *early-stage synovitis* is widely accepted. In fact, the definition of *early-stage* has evolved with time. Previously, studies used a cutoff of less than 5 years to define early-stage disease for RA. By the 1990s, duration of symptoms for less than 12 to 24 months was considered early stage. This duration was chosen because most RA patients incur significant damage when treated conventionally.

The window for modifying disease outcomes might be narrow, and maximum benefit might require interventions even earlier. Some evidence suggests that treatment within months might be beneficial.[3] For this reason, several early arthritis cohorts in recent years restrict the inclusion criterion of symptom duration and include only patients with a symptom onset of less than 12 weeks; this is referred to as *very early-stage synovitis*. Even this definition probably does not capture the earliest phase of the disease because circulating antibodies might appear years before the onset of symptoms in RA, and biomarkers reflecting bone destruction are elevated before arthritis is present.[4,5] Animal models show that histologic evidence of inflammation and activation of signaling pathways can occur well before clinically apparent disease.

Although the term *synovitis* generally refers to a swollen joint detected by physical examination, alternative definitions are also applied. Physical examination might not be sensitive enough to detect the condition, and clinically undetectable synovitis may be present and relevant to identify. Therefore some studies consider tenderness in the absence of swollen joints as synovitis. For instance, early arthritis clinics might include patients with tenderness but no swollen joints. Others determine synovitis not by physical examination but through the use of imaging modalities such as ultrasound or MRI. Different ultrasound techniques are used; of these, traditional B-mode grayscale ultrasonography provides information on synovial thickness, and Doppler imaging measures the synovial blood flow. Ultrasound is easily accessible, rapid, and inexpensive. An important consideration is the reproducibility between readers. Whereas some studies found good or acceptable inter-reader agreement, other studies observed considerable variation between readers. Ultrasound appears to be valuable, especially in the absence of abnormalities, and the negative predictive value of a normal ultrasound result is high. The prognostic implication of abnormal ultrasound findings is less clear.[6] More long-term studies are needed to establish which ultrasound characteristics have a high positive predictive value for the development of persistent or erosive arthritis.

Until more data become available, the term *early-stage synovitis* generally refers to synovitis that is detected by physical examination. It is important to note that early-stage synovitis refers to a sign and/or symptom but does not reflect a specific diagnosis. The spectrum of final diagnoses in a population of early synovitis patients is presented in Figure 72-1.

## EARLY-STAGE ARTHRITIS CLINICS

Early-stage arthritis clinics are population-based inception cohorts in which patients with synovitis of early onset are included and followed prospectively. These cohorts often

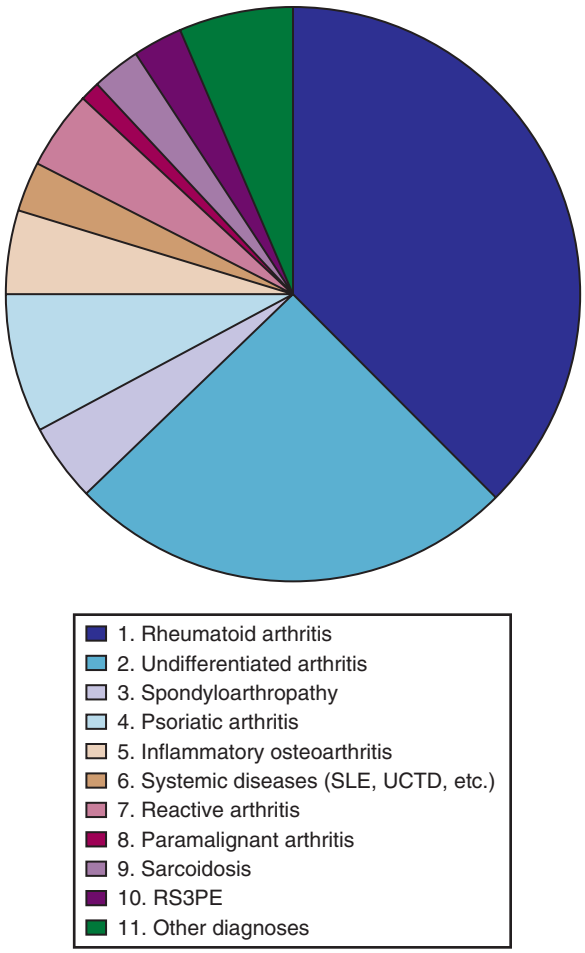

**Figure 72-1** Overview of diagnoses of early arthritis patients. (Presented data are based on 2284 early-stage synovitis patients included in the Leiden Early Arthritis Clinic cohort and their diagnosis after 1 year of follow-up.) RS3PE, Remitting seronegative symmetric synovitis with pitting edema; SLE, systemic lupus erythematosus; UCTD, undifferentiated connective tissue disease.

contain a wealth of phenotypic information, and the longitudinal design allows the study of factors related to a beneficial or severe course of the disease. Such studies might increase our understanding of the processes involved in arthritis progression. A summary of existing early arthritis cohorts is presented in Table 72-1. Inclusion criteria have changed with time, in parallel with changing interpretations of the term *early-stage*. Whereas the early arthritis clinics started in or before the 1990s allow inclusion of patients with symptoms for as long as 2 years, recently started early-stage arthritis clinics focus on very early-stage arthritis and include patients with symptoms for less than 12 weeks.

## WHAT IS UNDIFFERENTIATED ARTHRITIS?

The term *undifferentiated arthritis* (UA) refers to a subpopulation of early-stage synovitis patients who do not meet criteria for other diseases, including infections, spondyloarthropathies, crystal diseases, and RA. Because it is a diagnosis of exclusion, no classification criteria exist for UA.

European studies of early-stage arthritis cohorts found that 35% to 54% of the patients included do not meet the criteria for other diseases and are considered as UA[7,8]; in the remaining early-stage synovitis patients, a definitive diagnosis could be established at first visits. The frequency of UA depends on symptom duration at the time of the first visit to a rheumatologist. The longer symptoms have existed, the more likely it is that sufficient characteristics are present to support a definitive diagnosis, and the lower the prevalence of UA. In addition, the prevalence of UA will change when classification criteria for rheumatologic diseases change. For example, when the 1987 American College of Rheumatology (ACR) criteria for RA were applied to newly presenting early-stage synovitis patients in the context of an early-stage arthritis clinic in Europe (e.g., Leiden, the Netherlands), approximately 20% of those patients directly fulfilled the 1987 ACR criteria and thus were classified as RA. Initial data from the Leiden clinic suggest that this percentage is increased when the 2010 criteria for RA are applied.[9] The new criteria for RA not only might lead to a lower prevalence of UA, they also may lead to changed patient characteristics in the UA group. Those patients whose symptoms matched those of RA most closely may have been reclassified from UA to RA.[10,11]

### Characteristics of Early-Stage Undifferentiated Arthritis

Characteristics at first presentation in patients with early-stage UA and early-stage RA measured by using the 1987 criteria are somewhat different. Patients with recent-onset UA are younger (mean age, 48 vs. 57 years) and are less likely to be female (58% vs. 66%) than early-stage RA patients. UA patients generally have fewer swollen joints and have a greater likelihood of asymmetric synovitis. UA and RA patients do not differ in the acuteness of the start of their complaints, body mass index (BMI), or frequency of a positive family history for RA.[12] UA patients have fewer bone erosions at baseline; in a recent study, erosions were present in 18% of UA patients and 35% of RA patients.[13] Important differences were also noted with regard to autoantibodies. UA patients are RF positive in only 14% and anti-citrullinated protein antibody (ACPA) positive in 12% of cases, whereas both of these values are 55% in patients with early-stage RA.[6,7] According to both the 1987 and the 2010 classification criteria for RA, the presence of ACPAs in patients with arthritis is not equal to the classification of RA. Particularly in the case of monoarthritis or oligoarthritis, patients may not fulfill criteria for RA and are labeled as UA. However, about 70% of early-stage UA patients with ACPAs meet the 1987 ACR criteria 1 year later.

## REMISSION RATES IN EARLY-STAGE UNDIFFERENTIATED ARTHRITIS AND RHEUMATOID ARTHRITIS

The natural disease course of UA is variable, depending on the inclusion criteria and the duration of symptoms in several inception cohorts. Spontaneous remission occurs in 40% to 55% of UA patients. In contrast, the remission rate in RA is at most 10% to 15%.[14,15] In these studies, remission was defined as the absence of swollen joints for 1 year or

**TABLE 72-1** Overview of Early Arthritis Cohorts*

| Cohort | Inclusion Criteria | Year of Onset | Includes Early-Stage Arthritis (Symptoms <2 yr) | Includes Very Early-Stage Arthritis (Symptoms <3 mo) |
|---|---|---|---|---|
| Wichita Arthritis Center | Undifferentiated polyarthritis syndrome or RA<br>Disease duration <2 yr | 1973 | X | |
| Norfolk Arthritis Register | Early inflammatory polyarthritis<br>Age ≥16 yr<br>≥2 swollen joints<br>Symptom duration ≥4 wk | 1989 | X | |
| Leiden EAC | Synovitis of ≥1 joint<br>Symptom duration <2 yr<br>Age >16 yr | 1993 | X | |
| Austrian Early Arthritis Registry | Inflammatory arthritis<br>Symptom duration <12 wk | 1995 | | X |
| Amsterdam | Synovitis of ≥2 joints<br>Symptom duration <3 yr<br>Age >18 yr | 1995 | X | |
| Leeds Early Arthritis Centre | Undifferentiated arthritis of the hands<br>Symptom duration <12 mo | 1995 | X | |
| Birmingham VEAC | Synovitis of at least one joint<br>Symptom duration ≤3 mo | 2000 | | X |
| ESPOIR Cohort Study | Certain RA and UA that may develop into RA<br>Symptom duration <6 mo<br>Age 18-70 yr<br>≥2 inflammatory joints for the past 6 wk | 2002 | X | |
| Toronto Early Arthritis Cohort | Age >16 yr<br>Symptom duration between 6 wk and 12 mo<br>≥2 swollen joints or 1 swollen MCP or PIP joint with one or more of the following: positive RF, positive ACPA, morning stiffness >45 min, response to NSAIDs, or painful metatarsophalangeal squeeze test | 2003 | X | |
| Berlin EAC | ≥2 swollen joints<br>Symptom duration between 4 wk and 12 mo | 2004 | X | |
| Norwegian Very Early Arthritis (NOR-VEAC) | Synovitis of at least one joint<br>Symptom duration of 16 wk | 2004 | | X |
| New Castle EAC | Synovitis of at least one joint or inflammatory complaints without a synovitis at physical examination | 2006 | X | |
| Rotterdam Early Arthritis CoHort (REACH) | Synovitis ≥1 joint or ≥2 tender joints<br>Symptom duration ≤1 yr | 2007 | X | |

*The presented cohorts include not only early-stage RA patients but also a broader range of early-stage synovitis patients.
ACPA, Anti-citrullinated protein antibody; EAC, Early Arthritis Center; MCP, metacarpophalangeal; NSAIDs, nonsteroidal anti-inflammatory drugs; PIP, proximal interphalangeal; RA, rheumatoid arthritis; UA, undifferentiated arthritis.

longer after discontinuation of eventual disease-modifying anti-rheumatic drug (DMARD) therapy and/or discontinuation of participation in the outpatient clinic because the rheumatologist classified the patient as in remission. Longer-term follow-up is needed to determine whether symptoms recur many years later. In addition to the difference in frequency of spontaneous remission in UA and RA, the disease duration when spontaneous remission is achieved differs as well. A recent study observed that with UA, the median disease duration until spontaneous remission is 17 months, whereas in RA patients, the median period is 40 months before remission occurs.[12] Thus the chance of achieving a natural remission is reduced while the disease process matures. This supports the notion that chronicity might be more easily reversed in the undifferentiated phase of disease.

## JOINT DESTRUCTION IN EARLY-STAGE UNDIFFERENTIATED ARTHRITIS AND RHEUMATOID ARTHRITIS

Validated scoring methods are available to measure joint destruction objectively. Most scoring methods assess a limited number of joints. For example, the Sharp–van der Heijde method evaluates the metacarpophalangeal (MCP), proximal interphalangeal (PIP), wrist, and metatarsophalangeal (MTP) joints but does not evaluate the distal interphalangeal or larger joints. Therefore this method may be less optimal to measure the level of joint damage in patients who are seen with predominant synovitis in large joints. In RA, the extent of joint destruction in small joints adequately reflects joint destruction in larger joints. Such data are missing for UA patients.

Evaluation of the subgroup of UA patients in whom RA developed later in time provides insights that can help physicians to assess prognosis. Radiologic data were compared with those of patients who, when first seen by a physician for the disease, directly fulfilled the 1987 ACR criteria for RA. Radiographic progression rates between these groups were not different. Health Assessment Questionnaire (HAQ) scores and Disease Activity Score (DAS) measures also were not different between these two groups.[16] Thus, although UA patients as a group have a higher rate of spontaneous remission compared with patients with RA, the subgroup of UA patients who progress to RA have an equally severe course compared with patients classified as RA earlier in the disease. Studies that compare the rate of joint destruction in the total group of early-stage UA patients with that of patients with early-stage RA have not been performed.

## BIOLOGIC MECHANISMS IN UNDIFFERENTIATED ARTHRITIS AND DETERMINANTS OF PROGRESSION TO RHEUMATOID ARTHRITIS

Our understanding of the processes responsible for progression from UA to RA is far from complete. The following risk factors were identified as independent predictors for RA development and may provide clues:

- *Age:* The incidence of RA is clearly age dependent, with a rising incidence from 7 in 100,000 individuals for the age group 18 to 34 years to 107 in 100,000 individuals for the age group 75 to 84 years.[17] The reasons for this age-related increase are unknown. Possibilities include age-related alterations in cellular, humoral, and innate immunity.
- *Sex:* Women with UA have a twofold greater chance for RA compared with men who are seen with UA.[17] Sex hormones influence predisposition to autoimmune disease. In general, men are less prone than women. Androgens have anti-inflammatory effects, and estrogens have been reported to suppress arthritis as well.[18,19] Both estrogen and androgen inhibit bone resorption.[20] These results may account for increased progression in postmenopausal females.
- *Number of involved joints and C-reactive protein (CRP):* The number of affected joints and acute phase reactants like CRP reflects the level of inflammation and are frequently reported to be associated with progression of synovitis and worse disease outcomes. Although the number of swollen joints and the level of CRP are correlated on a group level, this is often not the case in individual patients, and both markers have their own independent predictive value. UA patients who are seen with CRP levels higher than 50 mg/L have a five times increased risk of being in an early stage of RA. Likewise, patients classified with UA who have polyarthritis have a 1.5 times increased chance of fulfilling the criteria for RA later on compared with patients with monoarthritis or oligoarthritis. Moreover, the risk that RA will develop in an early-stage UA patient who has more than 10 swollen joints is three times greater than that in patients with monoarthritis or oligoarthritis.
- *Autoantibodies:* The presence of autoantibodies in the serum of patients with RA has been recognized already for more than 70 years. Rheumatoid factors (RF) targeting the Fc part of human IgG were among the first group of autoantibodies discovered. Unfortunately, RF are not specific for RA and can be detected in as many as 15% of healthy individuals. In 1964 and 1979, additional serum factors present in RA patients were described: antiperinuclear factor antibodies and antikeratin antibodies, respectively. Although their specificity for RA was higher, assays to detect them were not routinely performed. Therefore RF was used to aid RA diagnosis in daily practice, and the presence of RF was incorporated into the ACR 1987 criteria for RA. It was not until 1995 when it was realized that antiperinuclear factors and the antikeratin antibodies recognize similar epitopes, and that they both target citrulline residues in proteins (i.e., ACPAs). ACPAs as well as can be present many years before the first clinical symptom of synovitis is noted; they are a risk factor for a persistent and destructive course of synovitis. Spontaneous remission is uncommon in $ACPA^+$ patients. Not only the presence but also the level of ACPAs has prognostic relevance. Despite these strong associations, studies that formally prove that ACPAs themselves are causally related to disease progression are lacking.

  Recently a new class of autoantibodies was identified that discriminates between citrulline- and homocitrulline-containing antigens in the sera of RA patients. IgG antibodies recognizing carbamylated (homocitrulline-containing) antigens were present in the sera of more than 45% of RA patients. Likewise, anti-carbamylated protein (anti-CarP) IgA antibodies were observed in 43% of RA sera. ACPA and anti-CarP antibodies are distinct autoantibodies because, in selected double-positive patients, the anti-CarP antibodies binding to carbamylated antigens could be inhibited by carbamylated antigens, but not by control or citrullinated antigens.[21] Anti-carbamylated protein (anti-CarP) antibodies precede the onset of RA in a subset of patients that are $ACPA^-$. When found in arthralgia patients, they are associated with the subsequent development of RA.[22,23,24]
- *Environmental factors:* Early-stage UA patients who smoke have a higher risk for RA and a destructive disease course. This risk is confined to patients who carry human leukocyte antigen (HLA)-DRB1 alleles that encode for the so-called *shared epitope*. Persons who smoke and also carry an HLA-DRB1 shared epitope allele are particularly prone to ACPAs, which subsequently are associated with disease persistency and erosiveness.
- *Genetic factors:* Apart from the HLA-DRB1 shared epitope alleles, genetic factors associated with progression from UA to RA are not clearly identified. Most genetic risk factors for RA provide risk for ACPA-positive RA when compared with healthy controls. It is not clear whether these factors are associated with progression from UA to RA as well, and if so, whether such an association is independent of the strong association between ACPAs and development of RA. Identification of new genetic factors has fueled the study of their relevance. In a population of UA patients, information on

currently known genetic risk factors for RA does not improve prediction of risk for RA compared with a prediction rule based on common clinical risk factors alone.[25]

- *Additional biomarkers:* The role of biomarkers in the diagnosis of UA is limited. Within RA, it is known that serologic levels of promatrix metalloproteinase 3 (MMP3), receptor activator of nuclear factor-κB (NF-κB) ligand (RANKL), and osteoprotegerin (OPG) correlate with the rate of joint destruction with time.[26] Biomarkers that specifically reflect or predict disease progression in early-stage UA patients thus far remain unknown. A prospective cohort of first-degree relatives of RA probands, which is a population without RA but at increased risk for its future development, was recently studied. Serum IL-6 and IL-9, IL-2, granulocyte macrophage-colony stimulating factor (GM-CSF), and interferon (IFN)-γ levels were associated with positive autoantibodies and could be used as a proxy for RA risk.[27]

## WINDOW OF OPPORTUNITY

The concept of a window of opportunity suggests that there is a period early in the course of the disease when the disease process can be altered or can even be reversed with a complete return to normality. Treatment during this period might have a greater effect than treatment at a later stage in terms of halting disease progression and achieving remission.[27-30] Several different aspects have been studied, including whether very early-stage UA (<12 weeks) may be an immunopathologically distinct phase compared with later disease.

Studies that focused on synovial tissue did not reveal differences.[31] It is difficult to come to a conclusion from negative studies because one never knows whether the relevant processes have been studied. However, studies that focused on the composition of autoantibody responses have demonstrated that profound maturation of the autoantibody response occurs early during disease.[32]

UA patients who are seen at an early-stage arthritis clinic within 12 weeks of symptom onset less often progress toward RA compared with UA patients with symptom duration of longer than 12 weeks. Similarly, RA patients who at their first visit to a rheumatologist reported symptoms for less than 12 weeks had a lower rate of joint destruction with time and achieved sustained DMARD-free remission more often than RA patients who reported a period of symptoms for longer than 12 weeks before seeing a rheumatologist.[33]

Support for the presence of a window of opportunity is also obtained from trials.[34] An open-label study of a single dose of corticosteroids in patients with mild early-stage inflammatory arthritis (median, 20 weeks) found that the strongest predictor of disease remission at 6 months (defined as the absence of symptoms and signs in patients without anti-inflammatory treatment) was disease duration less than 12 weeks at the time of therapy.[35] Clinical and radiologic outcomes were significantly better at 3 years in patients who started DMARD therapy within 3 months ("very early") after disease onset compared with a median duration of 12 months at the start of treatment ("early").[29] Remission was achieved in 50% of the very early-stage group compared with 15% of the early-stage group. These data suggest that treatment in very early-stage arthritis might have a greater effect on disease progression and thus underline the relevance of identification and treatment of arthritis in the very early-stage disease phase.

## TREATMENT OF UNDIFFERENTIATED ARTHRITIS

Although many rheumatologists have experience treating UA patients, formal data providing information on treatment of UA patients are lacking. A systemic literature review revealed eight randomized controlled trials (RCTs), two uncontrolled open-label trials, and three cohort studies. Temporary treatment with methotrexate (MTX), abatacept, and intramuscular corticosteroids were demonstrated in RCTs with 12 months to 5 years follow-up to be more effective than placebo in suppressing disease activity or radiologic progression. One study suggests that DMARD combination therapy is, at least after 4 months, superior to MTX monotherapy in patients with UA at high risk for persistent arthritis. The open-label uncontrolled trials and cohort studies also suggested that early treatment might provide immediate suppression of inflammation. The long-term benefit of early treatment in UA remains unclear, and RA ultimately develops in many patients if therapy is discontinued.[36]

The trials that have been performed in UA patients are summarized in Table 72-2. One trial observed an effect of steroids in early-stage UA patients—an observation that was not reproduced in another study. MTX is reportedly beneficial in UA patients and is associated with delayed progression to RA and a reduction in the rate of joint destruction. This effect appeared to be predominant among $ACPA^+$ UA patients but was negligible in $ACPA^-$ UA patients. However, as noted above, when MTX was discontinued, the rate progression to RA was similar to the placebo arm.

Some biologics have been studied in UA patients. Although surprising lack of efficacy was observed with TNF blockers, abatacept was beneficial. The heterogeneous nature of UA patients and the more favorable disease outcome and spontaneous remission rate make it difficult to observe treatment efficacy in the total UA group. Thus the placebo-treated group can have a good remission rate, and differences from the treatment group might be difficult to detect. None of the published randomized trials in UA patients addressed this problem of heterogeneity and stratified patients having a high chance of developing RA or of having a spontaneous remission.

### Individualized Treatment of Undifferentiated Arthritis

UA has a variable disease course, ranging from spontaneous remission to severe destruction. Because of this, and because DMARD therapy is potentially toxic, treatment of UA patients should be personalized. The chance for individual patients to progress toward RA or to have a persistent erosive disease course can be estimated by using prediction models.[37,38] One of the present prediction rules (Figure 72-2A) is validated by using data from early-stage arthritis clinics from Germany, the United Kingdom, Canada,

**TABLE 72-2** Randomized Controlled Trials in Patients with Early-Stage Undifferentiated Arthritis

| Trial | *n* | Treatment | Follow-up Duration | Outcome | Effect Compared with Placebo |
|---|---|---|---|---|---|
| SAVE trial[46] | 389 | Single IM injection of 120 mg methylprednisolone | 52 wk | Drug-free clinical remission | No effect |
| STIVEA trial[47] | 265 | 3 IM injections of 80 mg methylprednisolone | 6 and 12 mo | Need to start DMARDs | At 6 mo 61% vs. 76% had started DMARDs; At 12 mo 10% vs. 20% had resolved disease |
| PROMPT trial[48,53] | 110 | Methotrexate (MTX) therapy for a period of 12 mo | 60 mo | Fulfilling the 1987 ACR criteria | RA developed in 40% vs. 53%; lower radiologic progression |
| ADJUST trial[49] | 56 | Abatacept treatment for a period of 6 mo | 12 mo | Fulfilling the 1987 ACR criteria | RA developed in 46% vs. 67%; no effect on radiographic progression |
| Saleem et al[50] | 17 | Infliximab at 0, 2, 4, and 16 wk | 26 wk | Clinical remission | No effect observed |
| van Eijk *et al*[51] | 82 | Remission-targeted treatment vs. conventional care | 2 yr | Radiologic progression | Less progression |
| Improved[52] | 122 | MTX + tapered high-dose prednisone | 4 mo | DAS remission (<1.6) | Not applicable |
| TREACH [53] | 281 | MTX + oral GC vs. MTX+ SSZ + HCQ + oral GC vs. MTX+ SSZ + HCQ + i.m GC | 3 mo | DAS, HAQ | Combination better |

Russia, and Japan; this algorithm is currently used in daily practice in several countries.[37,39-44] The discriminative ability of this model is high. The prediction rule consists of nine variables: age, gender, distribution of involved joints, morning stiffness, numbers of tender and swollen joints, CRP level, and presence of RF and ACPAs. It calculates the risk of development of RA for every UA patient (see Figure 72-2B). Such information can facilitate the decision of whether or not to initiate DMARD therapy and might facilitate patient involvement in decision making. In general, a score of 6 or lower is related to a low chance that RA will develop (91% chance of that RA will not develop) and may be a reason to not initiate DMARD therapy. In contrast, patients with a score of 8 or higher have an 84% chance that RA will develop; this might be a reason to initiate DMARD therapy in some patients.

Can the 2010 ACR/European League against Rheumatism criteria[45] be used to identify UA patients who actually have early-stage RA? The presence of new criteria for RA is relevant in that the absence of up-to-date classification criteria had hampered progress with regard to treatment strategies in early-stage RA. The 1987 ACR criteria for RA were not designed to classify early-stage RA and did not include more recent autoantibody tests or imaging modalities. Most randomized clinical trials included patients who fulfilled the 1987 criteria, hence patients with established RA. It is not clear whether the efficacy observed in these trials is the same for patients with early-stage RA or UA. The new criteria have mainly been derived for classification and research purposes[45] and require validation for use in clinical practice for early-stage synovitis. The 2010 criteria should not be used as diagnostic criteria until it is demonstrated that patients who fulfill them have a high chance for a persistent or destructive disease course, making the 2010 criteria positivity the basis of an argument for starting disease-modifying drugs.

CHAPTER 73

# Sjögren's Syndrome

E. William St. Clair

**KEY POINTS**

- Sjögren's syndrome is divided into primary and secondary forms. The primary form occurs in approximately 0.1% to 0.6% of the general population.
- The clinical hallmarks of Sjögren's syndrome are keratoconjunctivitis sicca (dry eyes), xerostomia (dry mouth), and parotid gland swelling.
- Extraglandular features of primary Sjögren's syndrome include fatigue, Raynaud's phenomenon, polyarthralgia/arthritis, interstitial lung disease, neuropathy, and purpura.
- A chronic mononuclear cell infiltration of the lacrimal and salivary glands is the characteristic histopathologic finding.
- A diagnosis of primary Sjögren's syndrome is made by subjective and objective assessment of dry eyes and dry mouth, testing for serum anti-nuclear antibodies, including anti-Ro/SS-A and anti-La/SS-B antibodies, and labial salivary gland biopsy.
- Treatment of Sjögren's syndrome currently aims to provide symptomatic improvement in the symptoms of dry eyes and dry mouth, as well as control extraglandular manifestations of disease. Disease modifying therapy so far remains experimental.

## HISTORIC PERSPECTIVE

In 1888, Johann von Mikulicz-Radecki described a case of bilateral painless swelling of the lacrimal, parotid, and submandibular glands,[1] an entity that later bore his name. Reports soon followed showing that Mikulicz disease was not a distinct pathologic entity but rather a clinical potpourri of conditions, including leukemia, lymphoma, and tuberculosis. Shortly thereafter, salivary gland disease became linked with dryness of the eyes and oral mucosa when Henri Gougerot, a well-known and successful French dermatologist, wrote in 1925 about three cases of salivary gland atrophy with dryness of the eyes, mouth, and vagina. The modern concept of Sjögren's syndrome was firmly rooted in 1933 when Henrik Sjögren, a Swedish ophthalmologist, reported a series of 19 cases of keratoconjunctivitis sicca, including two cases with swelling of the major salivary glands.[2] During the next 2 decades, Sjögren and others published extensively on various facets of the disease that now carries his name (also called Gougerot-Sjögren disease), with most of these early contributions coming from European ophthalmologists.

In 1953, Morgan and Castleman[3] published their detailed histopathologic findings from 18 patients with enlarged lacrimal and salivary glands. This pathologic treatise consisted of cases with clinical features resembling those of Mikulicz's disease and Sjögren's syndrome. Notably, 15 of the 18 patients were women with lacrimal and salivary gland swelling that developed in the fifth and sixth decades of life. Morgan and Castleman found in the salivary gland tissue a consistent "lymphoid element" accompanied by a striking proliferation of myoepithelial and epithelial cells. The epithelial changes produced a characteristic narrowing or obliteration of the ductal lumen, forming cords of solid cell masses they called *epimyoepithelial islands*. Because of the prominence of these epithelial structures, Morgan and Castleman advanced the theory that Mikulicz disease had its origins in the ductal epithelium. The salivary gland pathology in these cases was similar to that of the patients with keratoconjunctivitis sicca described by Henrik Sjögren. Because Sjögren's patients were mostly middle-aged women, Morgan and Castleman reasoned that Mikulicz disease was a subset of Sjögren's syndrome but with incomplete clinical manifestations. This now classic paper had the effect of unifying Mikulicz disease and Sjögren's syndrome into a single disease entity, a belief that dominated thinking until recently.

When Joseph J. Bunim delivered the Heberden Oration at the Wellcome Foundation in London on December 2, 1960, he described in elegant detail the clinical, pathologic, and laboratory findings of the 40 patients with Sjögren's syndrome evaluated by himself, Kurt Bloch, Martin Wohl, Richard Oglesby, and Irwin Ship at the Clinical Center of the U.S. National Institutes of Health (NIH).[4] All patients in their series had at least two of the three following features: keratoconjunctivitis sicca, xerostomia (with or without enlargement of the salivary glands), and rheumatoid arthritis. Bunim also knew from the work of others that keratoconjunctivitis sicca and xerostomia, or sicca complex, occurred in some patients with systemic lupus erythematosus, scleroderma, polymyositis, and polyarteritis nodosa. In his lecture, he made the point that the exocrinopathy extended beyond the lacrimal and salivary glands to affect the pharynx, larynx, and trachea, as well as the vagina. Many of the patients with Sjögren's syndrome in the NIH cohort also had extraglandular manifestations, such as Raynaud's phenomenon, purpura, pulmonary infiltrates, and peripheral neuropathy. Talal and Bunim took note among the NIH cases of three patients with reticulum cell sarcoma (an older term that includes non-Hodgkin's lymphoma) and a fourth patient with Waldenström's macroglobulinemia, drawing attention for the first time to the increased risk for lymphoma in this disease.[5] In this report, they speculated

that a "chronic state of immunologic hyperactivity and the proliferation of immunologically competent cells producing abnormal tissue antibodies predisposes to the relatively frequent development of malignant lymphoma."[5]

The NIH group also characterized the serologic markers of Sjögren's syndrome. In 1965 they reported that 12 of their 16 patients (75%) with sicca symptoms but no evidence of another connective tissue disease had serum anti-nuclear antibody (ANA) reactivity by indirect immunofluorescence on rat liver tissue.[6] Applying the Ouchterlony plate method, they further showed that sera from 13 of 16 (81%) of these patients contained precipitating antibodies to SjD and SjT, self-antigens subsequently named Ro (SS-A) and La (SS-B). Moreover, Bloch and colleagues[7] set the stage for our modern classification schemes by subdividing their patients into primary and secondary Sjögren's syndrome. Secondary Sjögren's syndrome referred to patients with sicca symptoms in the setting of another connective tissue disease, such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma, or dermatomyositis, whereas primary Sjögren's syndrome was the designation when the sicca complex occurred in the absence of another connective tissue disease.

In the late 1960s and early 1970s, studies of labial salivary gland biopsy as a diagnostic test for Sjögren's syndrome led to grading systems for quantifying tissue inflammation. In 1968, Chisholm and Mason proposed a grading system for labial salivary gland biopsies that used a simple grading scale (0 to 4), in which grades 0, 1, and 2 represented absent, slight, and moderate mononuclear cell infiltrates, respectively.[8] The higher grades of 3 and 4 corresponded to focal inflammatory cell scores of 1 or more per 4 $mm^2$ of tissue, in which a focus equated to an aggregate of 50 or more mononuclear cells. In this initial study, 9 of the 10 patients with Sjögren's syndrome were classified as grade 3 or grade 4. By comparison, biopsies with lower grades came from patients with other chronic inflammatory conditions, as well as controls. For example, among 10 patients with rheumatoid arthritis, the highest biopsy grade was only 3. Twenty other patients with a variety of other rheumatic diseases (e.g., osteoarthritis, reactive arthritis, psoriatic arthritis, and scleroderma) had biopsies with grades of 0 or 1. Although it was a small study by today's standards, this work inspired others to validate and refine these findings. Later, post-mortem biopsies from 116 controls with no history of inflammatory disease were scored as having only grade 0, 1, or 2 infiltrates, attesting to the diagnostic specificity of this grading system.[9] However, the Chisholm and Mason grading system had limitations because it was sensitive only at the lower end of the scale and did not distinguish among biopsies with the highest degree of cellular infiltrates or biopsies with two or more foci per 4 $mm^2$ of tissue.

To improve on these earlier efforts, Tarpley and co-workers[10] at the NIH developed a grading system that incorporated scales that not only estimated the extent of inflammation but also quantified the amount of acinar gland destruction. As expected, they found that labial salivary gland biopsies from patients with the sicca complex alone had higher grades of cellular infiltrates and acinar destruction than those with sicca symptoms and rheumatoid arthritis or rheumatoid arthritis alone. However, grading the acinar destruction did not add diagnostic value independent of the severity of the infiltrates. Greenspan and colleagues[11] from the University of California at San Francisco modified the Chisholm and Mason grading scale when they examined labial salivary gland biopsies from 54 patients with definite or probable Sjögren's syndrome together with 21 controls. Their results reinforced the diagnostic relevance of the focus score, including its relationship to focus size, and highlighted the presence of germinal centers (GCs).[11] Grade 4 biopsies (>1 focus per 4 $mm^2$ of tissue) were primarily found in the patients with Sjögren's syndrome, with the highest focus scores in patients with the sicca complex in the absence of another connective tissue disease. The range for the focus score was extended from 1 to 12, in which a score of 12 was arbitrarily assigned to specimens with foci so numerous that they were confluent. The focus score was thereafter adopted as the "gold standard" to quantify chronic inflammation in labial salivary gland biopsies. Other methods were examined to determine salivary gland involvement in Sjögren's syndrome, such as sialometry, chemical analysis of the saliva, sialography, and scintigraphy. However, these measures of salivary secretion and the imaging of duct anatomy proved to be diagnostically nonspecific; sialography and scintigraphy had other shortcomings that limited their clinical use.

With a growing interest in Sjögren's syndrome, investigators began to develop classification criteria for comparison of results across studies. In the 1980s, many groups proposed classification criteria for Sjögren's syndrome. These proposed criteria incorporated the following items: symptoms of the ocular and oral components, objective measures of lacrimal and salivary gland involvement, a focus score of 1 or more obtained from a labial salivary gland biopsy, and the presence of serum autoantibodies. Many investigators from Europe, the United States, and Japan contributed to this effort, leading to the general acceptance in 2002 of the revised version of the European criteria proposed by the American-European Consensus Group (AECG).[12] In 2012, new classification criteria were proposed by the International Sjögren's Syndrome Registry that have been provisionally accepted by the American College of Rheumatology (ACR),[13] which is the latest effort to improve disease classification.

## DEFINITIONS AND CLASSIFICATION CRITERIA

The clinical hallmarks of Sjögren's syndrome are keratoconjunctivitis sicca and xerostomia, or the sicca complex. The term "keratoconjunctivitis sicca" is derived from Latin, and its translation is "dryness of the cornea and conjunctiva." Xerostomia refers to the subjective symptoms of dry mouth. Sjögren's syndrome is subdivided into primary and secondary Sjögren's syndrome. Secondary Sjögren's syndrome describes patients with keratoconjunctivitis sicca, xerostomia, or both, in the setting of another connective tissue disease or chronic inflammatory process, such as rheumatoid arthritis, systemic lupus erythematosus, polymyositis, systemic sclerosis (scleroderma), or granulomatosis with polyangiitis. Patients are diagnosed with primary Sjögren's syndrome if they manifest signs and symptoms of keratoconjunctivitis sicca and xerostomia in the absence of another

connective tissue disease, provided they also meet serologic or histopathologic criteria. Because primary Sjögren's syndrome is associated with extraglandular features that overlap with those of other connective tissue diseases, it may be difficult in some cases to distinguish from secondary Sjögren's syndrome. The challenge in distinguishing between primary and secondary forms of the disease arises most often in patients with primary Sjögren's syndrome and overlapping features of lupus such as rash, arthritis, and leukopenia. This distinction may boil down to semantics, depending on the penchant for "lumping" or "splitting."

Other descriptors for Sjögren's syndrome are *autoimmune exocrinopathy*[14] and *autoimmune epithelitis*.[15] The term *exocrinopathy* emphasizes the generalized glandular involvement in this disease, which affects not only the lacrimal and salivary glands, but also the apocrine sweat glands of the skin and the submucosal glands of the nose, pharynx, larynx, large airways, and vagina. The term *epithelitis* gains footing from the activated epithelial cells seen in the lacrimal and salivary gland tissue and at other sites of glandular involvement.

By the early 1980s, several sets of criteria had been proposed to classify Sjögren's syndrome, including the Copenhagen criteria,[16] the Japanese criteria,[17] the Greek criteria,[18] and the California criteria.[19] Common to each of these criteria sets was the requirement for objective evidence of keratoconjunctivitis sicca and salivary gland involvement. They differed, however, in their item content and weighting, as well as the methods for assessing salivary gland involvement. Movement toward consensus began when the Epidemiology Committee of the European Community conducted a multicenter study involving 26 centers from 12 countries aimed at unifying criteria for the classification of Sjögren's syndrome. This group first agreed on the items that should be included in the classification criteria for Sjögren's syndrome and then tested their operational characteristics in a large sample of patients with a clinical diagnosis of primary Sjögren's syndrome ($n = 246$), secondary Sjögren's syndrome ($n = 201$), other connective tissues diseases without Sjögren's syndrome ($n = 113$), and healthy controls ($n = 133$).[20] Two sets of three questions were selected from a larger body of questions that best correlated with the presence of keratoconjunctivitis sicca and xerostomia, respectively, as judged by clinical experts. The results from objective tests were analyzed by univariate analyses, yielding a tentative list of items based on their sensitivity and specificity for correct classification of the diagnosis. The following six items were chosen for the classification criteria: (I) ocular symptoms; (II) oral symptoms; (III) ocular signs (Schirmer-I test ≤5 mm/5 min or Rose Bengal score ≥4 by the van Bijsterveld scoring system); (IV) histopathologic features (focus score ≥1 on labial salivary gland biopsy; (V) objective evidence of salivary gland involvement by at least one abnormal test (salivary scintigraphy, parotid sialography, or unstimulated salivary flow rate ≤1.5 mL/15 min); and (VI) at least one of the following serum autoantibodies: anti-Ro/SS-A or anti-La/SS-B antibodies, ANAs, or rheumatoid factor. Exclusion criteria were pre-existing lymphoma, acquired immunodeficiency syndrome, sarcoidosis, and graft-versus-host disease. The presence of four of six criteria (accepting only a positive test for anti-Ro/SS-A or anti-La/SS-B antibodies for item VI) had good sensitivity (93.5%) and specificity (94%) for correctly classifying a patient with primary Sjögren's syndrome. It was suggested to be the optimal combination for efficient classification of this condition. For classification of secondary Sjögren's syndrome, the best combination was found to be a positive response for items I or II plus a positive result for any two of items II, IV, and V, resulting in a sensitivity of 85.1% and specificity of 93.9% for this diagnosis.

These preliminary European classification criteria for Sjögren's syndrome were validated in a second study of similar design. Cases of primary Sjögren's syndrome ($n = 81$), secondary Sjögren's syndrome ($n = 76$), other connective tissue diseases without Sjögren's syndrome ($n = 54$), and controls ($n = 67$) were assembled by expert clinicians at 16 centers from 10 countries to validate the initial results.[21] In this study, it was decided not to use items III (a) (Schirmer-I test) and V (c) (unstimulated whole salivary flow) to classify patients older than age 60 years because the tear and salivary flow by these measures were significantly reduced in the elderly controls from the original cohort. The results were similar to those of the earlier study, showing a sensitivity of 97.5% and specificity of 94.2% for correct classification of primary Sjögren's syndrome and a sensitivity of 97.3% and specificity of 91.8% for correct classification of secondary Sjögren's syndrome. A limitation of this type of study design is that the sensitivity and specificity may be artificially inflated by a "circular bias." These preliminary European classification criteria have also been criticized because a patient may be classified with primary Sjögren's syndrome despite a negative biopsy and the absence of serum anti-Ro/SS-A or anti-La/SS-B antibodies.

This conceptual impasse was overcome by the European Study Group on Classification Criteria for Sjögren's Syndrome with a group of American experts. From their previous study, they selected a cohort of 76 patients with primary Sjögren's syndrome, 41 patients with another connective tissue disease but without Sjögren's syndrome, and 63 controls, and tested three different combinations of items from the original classification criteria using a receiving operator curve (ROC) analysis. Based on the ROC analyses, patients may now be classified with primary Sjögren's syndrome if they fulfill four of the six items, including either a positive labial salivary gland biopsy or a positive test for serum anti-Ro/SS-A and/or anti-La/SS-B antibodies. This combination avoids the problem of classifying a patient with primary Sjögren's syndrome in the absence of a positive labial salivary gland biopsy or a positive test for anti-Ro/SS-A and/or anti-La/SS-B antibodies. Alternatively, they may meet the criteria by satisfying any four of the objective items, which was a highly unusual scenario in their data set.

The revised classification criteria proposed by the AECG are shown in Table 73-1. It was further specified that the Schirmer-I test be performed with anesthesia and that other ocular dyes, such as lissamine green (for conjunctival staining) and fluorescein (for corneal staining), should be allowed as replacements for Rose Bengal dye, which was not available in many countries. A positive labial salivary gland biopsy was further defined according to the rules set forth by Daniels and Whitcher.[22] In this case, a positive biopsy must show evidence of focal lymphocytic sialadenitis (FLS), which was defined as dense aggregates of 50 or more

**TABLE 73-1** Revised International Classification Criteria for Sjögren's Syndrome (SS)

I. Ocular symptoms: a positive response to at least one of the following questions:
   1. Have you had daily, persistent, troublesome dry eyes for more than 3 months?
   2. Do you have a recurrent sensation of sand or gravel in the eyes?
   3. Do you use tear substitutes more than 3 times a day?

II. Oral symptoms: a positive response to at least one of the following questions:
   1. Have you had a daily feeling of dry mouth for more than 3 months?
   2. Have you had recurrently or persistently swollen salivary glands as an adult?
   3. Do you frequently drink liquids to aid in swallowing dry food?

III. Ocular signs—that is, objective evidence of ocular involvement defined as a positive result for at least one of the following two tests:
   1. Schirmer-I test, performed without anaesthesia (≤5 mm in 5 minutes)
   2. Rose Bengal score or other ocular dye score (≥4 according to van Bijsterveld's scoring system)

IV. Histopathology: in minor salivary glands (obtained through normal-appearing mucosa), focal lymphocytic sialoadenitis, evaluated by an expert histopathologist, with a focus score greater than 1, defined as a number of lymphocytic foci (which are adjacent to normal-appearing mucous acini and contain more than 50 lymphocytes) per 4 $mm^2$ of glandular tissue

V. Salivary gland involvement: objective evidence of salivary gland involvement defined by a positive result for at least one of the following diagnostic tests:
   1. Unstimulated whole salivary flow (≤1.5 mL in 15 minutes)
   2. Parotid sialography showing the presence of diffuse sialectasias (punctate, cavitary or destructive pattern), without evidence of obstruction in the major ducts
   3. Salivary scintigraphy showing delayed uptake, reduced concentration, and/or delayed excretion of tracer

VI. Autoantibodies: presence in the serum of the following autoantibodies:
   1. Antibodies to Ro(SS-A) or La(SS-B) antigens, or both

**Revised Rules for Classification**

**For Primary SS**

In patients without any potentially associated disease, primary SS may be defined as follows:
   a. The presence of any 4 of the 6 items is indicative of primary SS, as long as either item IV (histopathology) or VI (serology) is positive.
   b. Any three of the four objective criteria items (i.e., items III, IV, V, and VI) are present.
   c. The classification tree procedure represents a valid alternative method for classification, although it should be more properly used in clinical-epidemiologic surveys.

**For Secondary SS**

In patients with a potentially associated disease (e.g., another well-defined connective tissue disease), the presence of item I or item II plus any two from items III, IV, and V may be considered indicative of secondary SS.

**Exclusion Criteria**

Past head and neck radiation treatment
Hepatitis C infection
Acquired immunodeficiency syndrome
Pre-existing lymphoma
Sarcoidosis
Graft-versus-host disease
Use of anticholinergic drugs (since a time shorter than fourfold the half-life of the drug)

From Vitali C, Bombardieri S, Jonsson R; the European Study Group on Classification Criteria for Sjögren's Syndrome: Classification criteria for Sjögren's syndrome: a revised version of the European criteria proposed by the American-European Consensus Group. *Ann Rheum Dis* 61:554–558, 2002.

lymphocytes in perivascular or periductal locations. These aggregates, or foci, must contain only a small proportion of plasma cells and be located adjacent to normal-appearing acini in lobules without duct dilatation or fibrosis. A minimum threshold for positivity was considered to be greater than or equal to 1 focus per 4 $mm^2$ of tissue. These rules are important to follow because many biopsy specimens, especially from elderly individuals, show patterns of inflammation consistent with chronic sialadenitis, namely mixed lymphocytic and plasma cell infiltrates in association with ductal dilation, acinar atrophy, and fibrosis.

An abnormal parotid sialogram has been clarified in the revised criteria as the presence of diffuse sialectasis according to the scoring system of Rubin and Holt.[23] Positivity by salivary scintigraphy was also further defined as delayed uptake, reduced concentration, or delayed secretion of the tracer, by using the method of Schall and colleagues.[24] Parotid sialography and salivary scintigraphy, however, are rarely used clinically in the United States. The revised version also included some modifications to the list of exclusion criteria.

The revised criteria have also not escaped criticism by some experts because of the possibility that patients may be classified as having primary Sjögren's syndrome without subjective or objective evidence of ocular involvement (satisfying items IV, V, and VI).[25] Others have mentioned the "histologic and immunologic bias" of the revised criteria.[26] Some patients with primary Sjögren's syndrome test positive for serum ANAs in the absence of anti-Ro/SS-A and anti-La/SS-B antibodies. If such patients have a falsely negative labial salivary gland biopsy, then they will not be classified with primary Sjögren's syndrome, despite a better than average chance otherwise. Another potential shortcoming is the lack of laboratory standardization for the detection of anti-Ro/SS-A and anti-La/SS-B antibodies. Many different methodologies are available to measure these autoantibodies, including the older Ouchterlony plate assay, various commercial enzyme-linked immunosorbent

assay (ELISA) kits, and the newer multiplex bead technology. ELISA and the multiplex bead assays are used by nearly all of the hospital and commercial laboratories. It is unclear whether the type of methodology influences the sensitivity or specificity of these criteria. Although these classification criteria have been generally accepted by the medical community, they have not been officially endorsed by the ACR or the European League against Rheumatism (EULAR).

Recently, new classification criteria have been published based on data from 1362 participants in the Sjögren's International Collaborative Clinical Alliance Cohort (SICCAC).[13] These criteria have been provisionally approved by the ACR pending their validation. These criteria are derived solely from objective test results and do not require symptoms of dry eyes or dry mouth. To meet the classification of primary Sjögren's syndrome, patients must have at least two of the following: (1) a positive test for serum anti-Ro/SS-A and/or anti-La/SS-B antibodies or a positive test for rheumatoid factor and an ANA titer of greater than or equal to 1:320, (2) labial salivary gland biopsy exhibiting focal lymphocytic sialadenitis with a focus greater than or equal to 1 per 4 $mm^2$, and (3) keratoconjunctivitis sicca with ocular staining score greater than or equal to 3. By using an external set of 303 participants, these classification criteria had a sensitivity of 92.5% and a specificity of 95.4%. The 2012 criteria have been criticized as unduly invasive because they require a slit lamp exam and corneal staining and/or lip biopsy, but they are classification criteria designed for the research environment and not for diagnosis.

The operating characteristics of the 2002 AECG and 2012 SICCAC/ACR have been compared in two studies. One study examined 646 participants, 279 of whom met the AECG criteria and 268 of whom met the SICCAC/ACR criteria. There was agreement regarding the classification of 244 of 279 patients (81%). The difference in ocular staining score (ACR ≥3/12 vs. AECG ≥4/9) was a source of discrepancy between the two classification schemes. Among the 35 patients who were classified positive by the AECG criteria but not the ACR criteria, 26 (74.3%) had insufficient ocular staining. Among the 24 patients who met the ACR criteria but not the AECG criteria for Sjögren's syndrome, 17 (70.8%) did so because of differences in the ocular staining score or serologic testing; 7 (29%) meeting the ACR criteria but not the AECG criteria tested positive for ANA and rheumatoid factor but not anti-Ro/SS-A or anti-La/SS-B antibodies.[27] Similar results were found in another study of 105 patients, 42 of whom met the AECG criteria and 36 the ACR criteria; 27 of whom met both. This study also found that a major source of disagreement between the two criteria sets was the different cut-off for ocular staining.[28]

## EPIDEMIOLOGY

Primary Sjögren's syndrome ranks among the most common of the autoimmune diseases, with a prevalence rate ranging from 0.1% to 4.6%.[29,30] However, the epidemiologic data are confounded by variations in the ages of the study populations and differences in the classification criteria used for case identification. Bowman and colleagues[31] estimated the prevalence of primary Sjögren's syndrome at 0.1% to 0.6% in a community from the United Kingdom by using the revised AECG criteria. In a study from Greece that used these same criteria, the age-adjusted mean annual incidence and prevalence rates were 5.3 (confidence interval [CI], 4.5 to 6.1) per $10^5$ people (0.5 for men and 10.1 for women) and 92.8 per 100,000 people (8.4 for men and 177.4 for women), respectively.[32] The incidence and prevalence rates of primary Sjögren's syndrome are significantly higher in women than men (e.g., approximately 20:1), with a peak incidence in the fifth and sixth decades of life.[32] Both gender ratio and age distribution appear to depend on the ethnicity and geographic region of the study population.[33] Primary Sjögren's syndrome occurs infrequently in children, with onset as early as 5 years.[34] The revised AECG criteria may be less sensitive for classifying primary Sjögren's syndrome in children than adults because of differences between these two age groups in the clinical presentation of this disease.[34]

The prevalence of secondary Sjögren's syndrome in patients with rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis has been estimated at 17.1%,[35] 8% to 20%,[36-38] and 14%[39]; respectively. To be classified with secondary Sjögren's syndrome, patients must have symptoms of keratoconjunctivitis sicca or xerostomia and objective evidence of lacrimal or salivary gland involvement.

## ETIOLOGY AND PATHOGENESIS

In primary Sjögren's syndrome, a common theme among models of disease pathogenesis is loss of immunologic tolerance to self-antigens. This breakdown in tolerance is evident in primary Sjögren's syndrome from the production of serum autoantibodies. Because the appearance of serum autoantibodies may precede the onset of clinical disease, the loss of immune tolerance appears to be permissive but not sufficient to induce tissue inflammation and damage. T cells reactive with several candidate self-antigens infiltrate the labial salivary glands of patients with primary Sjögren's syndrome. However, the timing of the evolution of these aberrant T cell responses is unclear with respect to disease onset. Environmental or stochastic factors or both are likely at play in triggering the chronic inflammatory response in the context of a genetically predisposed innate and adaptive immune system.

Because a disproportionately high number of the cases of primary Sjögren's syndrome occur in women, the search for environmental triggers has included studies of abnormal regulation of estrogens and androgens. However, no major differences have been found between patients with primary Sjögren's syndrome and healthy controls in serum levels of sex steroid hormones.[40] In addition, treatment with the hormone dehydroepiandrosterone, which acts on the androgen receptor, has shown no clinical efficacy in women with primary Sjögren's syndrome.[41] Among possible viral triggers, Epstein-Barr virus (EBV) and cytomegalovirus (CMV) have received attention in primary Sjögren's syndrome because of their suppressive effects on T cell immunity and their ability to establish persistent infection. In one study, EBV DNA was found by immunochemical staining in salivary gland biopsies to localize in acinar and ductal epithelial cells[42]; however, the available evidence does not otherwise support a direct role for EBV infection in the pathogenesis of this disease. A 94-base pair (bp) fragment

of coxsackievirus RNA was also differentially expressed in salivary gland biopsies from patients with primary Sjögren's syndrome compared with controls,[43] but these results were not replicated in a later study.[44] If one truly exists, the identity of a possible viral trigger remains elusive.

## Genetics

It has been difficult to estimate the genetic risk for primary Sjögren's syndrome because of the absence of large twin studies. However, the existence of many large families with two or more members with primary Sjögren's syndrome is strong evidence for a genetic component to disease pathogenesis.[45] Primary Sjögren's syndrome is considered a complex genetic disorder, similar to the genetic susceptibility of systemic lupus erythematosus and rheumatoid arthritis. It is now clear from genetic studies of human autoimmune diseases that multiple genes contribute to disease risk and that individually each gene confers only modest effects on disease susceptibility.[46] An exception to this rule is the relatively strong signal associated with the human leukocyte antigen (HLA) locus on human chromosome 6p21.3. In populations of European descent, confirmed HLA associations with primary Sjögren's syndrome include DRB1*0301 (DR3), DRB1*1501 (DR2), DQA1*0103, DQA1*0501, DQB1*0201, and DQB1*0601.[47,48] The disease-associated polymorphisms located in the DRB1*0301 and DRB1*1501 loci account for 90% of the HLA genetic contribution. The HLA locus appears to play a major role in the pathogenesis of autoantibody responses in primary Sjögren's syndrome. In a cohort of patients with this disease, higher titers of anti-Ro/SS-A and anti-La/SS-B antibodies were linked to heterozygosity for the DQA1 and DQB1 alleles.[49]

The genetic susceptibility to primary Sjögren's syndrome includes inheritance of genes identified as risk factors in other autoimmune diseases. Familial clustering of cases of primary Sjögren's syndrome with systemic lupus erythematosus, rheumatoid arthritis, and systemic sclerosis, as well as other autoimmune diseases, is consistent with these findings.[50-52] Initial efforts to identify disease susceptibility genes in primary Sjögren's syndrome relied on the candidate gene approach. More recently, however, collaborative research networks have been formed to generate large enough sample sizes for genome-wide association studies (GWAS). In one study of 395 individuals with primary Sjögren's syndrome and 1975 population controls of European descent, a strong association was confirmed for the HLA region, with allelic variants at HLA-DQB1*0201, HLA-DQA1*0501, and HLA-DRB1*0301 accounting mainly for this association.[53] Other genes conferring a disease risk in this study, albeit with a lower peak effect, included those encoding interferon (IFN) regulatory factor 5 (IRF5), signal transducers and activator of transcription 4 (STAT4), interleukin (IL)-12A, B lymphoid tyrosine kinase (BLK), C-X-C chemokine receptor type 5 (CXCR5), and TNFAIP3-interacting protein 1.[53] Another GWAS in Han Chinese identified GTF2I as a new susceptibility locus in primary Sjögren's syndrome, and confirmed the previously reported associations with STAT4, TNFAIP3, and the major histocompatibility locus in Europeans.[54] GTF2I encodes TFII-I, which is a phosphoprotein involved in B and T cell signaling pathways.

Genes in the type I IFN pathway are of interest in primary Sjögren's syndrome because they are highly expressed in the peripheral blood and salivary glands of patients with this disease compared with controls.[55] IRF5 in particular is a transcription factor that induces the transcription of IFN-α and the production of several proinflammatory cytokines, including IL-12-p40, IL-6, and TNF. It is among the nine IRFs that signal through Toll-like receptors (TLRs) and is essential for inducing responses through TLR4, 7, and 9.[56] Given the possible inciting roles of viral RNA and DNA, the endosomal TLR7 and TLR9 pathways may activate the type I IFN pathway in primary Sjögren's syndrome.[57] An increased risk of primary Sjögren's syndrome has been associated with a single nucleotide polymorphism in the splicing sequence of exon B of the gene encoding IRF5.[58] A 5-bp insertion/deletion polymorphism (CGGGG insertion/deletion) in the promoter region of the IRF5 transcript has also been linked to primary Sjögren's syndrome.[59] This polymorphism appears to have functional significance because reovirus (double-stranded RNA virus)–infected salivary gland epithelial cells in culture bearing this polymorphism produce higher levels of the IRF5 transcript.[59]

STAT4, a transcription factor involved in IL-12 and IL-23 signaling, is known to promote the development of T helper (Th)1 and Th17 responses. In a case-control study, an increased risk for primary Sjögren's syndrome was associated with a variant haplotype of the transcription factor STAT4.[60] This STAT4 polymorphism increases the risk for systemic lupus erythematosus and rheumatoid arthritis and correlates with the variant identified in the GWAS study of primary Sjögren's syndrome from Europe. Polymorphisms in the *STAT4* and *IRF5* genes appear to be additive in the risk for primary Sjögren's syndrome.[61] IL-12A, another player in the type I IFN pathway, encodes the p35 subunit of the IL-12 heterodimer (p35/p40), which is secreted mainly by monocytes and dendritic cells and is important for Th1 cell differentiation.

BLK is a Src family tyrosine kinase involved in B cell development. Nordmark and colleagues[62] have identified three other B cell–related gene loci associated with an increased risk of primary Sjögren's syndrome—the early B cell factor *(EBF1)* gene, the interval encompassing family with sequence similarity 167 member A and B lymphoid tyrosine kinase *(FAM167A-BLK)*, and the tumor necrosis family member 4 (TNFSF4, or the *OX40L* gene). All three genes are involved in B cell development and in theory might contribute to the hyperactivated state of B cells in this disease. CXCR5, a risk allele identified in a GWAS, is a chemokine receptor expressed on the surface of B cells and follicular helper T cells. In primary Sjögren's syndrome, its expression is upregulated in the salivary gland, where it may promote formation of GC-like structures and T cell–dependent B cell responses.

The human genome contains conserved noncoding elements with functional sequences, including regulatory motifs in promoters and untranslated regions of genes. Some of these conserved noncoding elements encode microRNAs that may regulate gene expression. MicroRNAs influence both innate and adaptive immunity and play a role in late B cell differentiation and development, as well as the establishment of B cell tolerance. Early studies have shown that

microRNA expression patterns in salivary gland tissue can distinguish patients with Sjögren's syndrome from controls, suggesting a pathologic role for microRNAs in the regulation of the chronic inflammatory response.[63]

Epigenetics refers to the study of inherited changes in gene expression caused by mechanisms other than a change in DNA sequence of that gene. Its principal mechanisms include remodeling of chromatic structure by DNA methylation and histone modification. Thus far, little is known about the epigenetics of primary Sjögren's syndrome.

## Adaptive and Innate Immunity

Many insights have been gained about disease mechanisms in primary Sjögren's syndrome in animal models as well as humans with this disease. Experiments in model systems enable hypotheses to be examined in ways not possible in humans, and have contributed to our understanding of the immunoregulatory disturbances underlying the clinical expression of disease (Table 73-2).[64,65] Although animal studies have shed light on possible disease mechanisms, it has been possible to perform highly significant research in humans because of the accessibility of labial salivary gland tissue from patients for immunohistopathologic analysis. Studies of labial salivary gland biopsies from patients with primary Sjögren's syndrome have shown approximately 90% of the infiltrating cells are $CD4^+$ T lymphocytes and B lymphocytes, with the remainder an admixture of plasma cells, $CD8^+$ T cells, $FoxP3^+$ T regulatory cells, $CD56^+$ natural killer (NK) cells, and macrophages, as well as myeloid and plasmacytoid dendritic cells (DCs)[66] (Figure 73-1). Most of the infiltrating T cells bear the memory phenotype (CD45RO) and display a restricted T cell receptor (TCR) repertoire representing several different clonotypes across

**TABLE 73-2** Mouse Models of Sjögren's Syndrome*

| Mouse Model | Phenotype | Comments |
|---|---|---|
| **Spontaneous Disease Models** | | |
| (NZB)NZW F1 mice | Progressive focal sialadenitis | Glandular involvement F > M |
| MRL/*lpr* | Lymphocytic infiltration of lacrimal and salivary glands; anti-Ro/SS-A and M3R antibodies; oligoclonal expansion of T cells and IgA and IgM production in the salivary glands | Normal secretory function; mRNAs for IL-1 and TNF expressed in salivary glands before onset of sialadenitis |
| NOD and its derivatives NOD.H2h4, NOD.Q, and NOD.P, NOD.E2fl$^{-/-}$, NOD.*scid* | Lymphocytic infiltration of lacrimal and salivary glands; NOD.H2h4 strain (but not parental NOD strain) secretes high levels of anti-Ro/SS-A and anti-La/SS-B antibodies; reduced glandular function | Mice also develop diabetes; exchange of H2 haplotype from H2g7 to H2q (NOD.Q) or H2p (NOD.P) does not affect the frequency of sialadenitis; disruption of ICA69 locus prevents lacrimal gland inflammation and reduces salivary gland inflammation; NOD IFN-$\gamma^{-/-}$ mice do not develop glandular disease; blockade of LT-βR signaling pathway reduces salivary gland infiltrates and improves salivary gland function |
| NFS/*sld* | Lymphocytic infiltration of lacrimal and salivary glands; anti–α-fodrin antibodies | Aberrant immune responses to α-fodrin; mice develop autoimmune lesions in other organ systems |
| **Experimentally Induced Models** | | |
| Carbonic anhydrase (PL/J mice) | Lymphocytic infiltration of salivary glands; antibodies to carbonic anhydrase | |
| Ro peptides (Balb/c mice) | Lymphocytic infiltration of salivary glands; glandular hypofunction, anti-Ro/SS-A and anti-La/SS-B antibodies | Disease induction requires multiple injections of peptide emulsified in Freund's adjuvant |
| **Transgenic or Knockout Models** | | |
| Id3$^{-/-}$ | Lymphocytic infiltration of lacrimal and salivary glands; adoptive transfer experiments; anti-Ro/SS-A and anti-La/SS-B antibodies; salivary hyposecretion | *Id3* gene involved in TCR-mediated T cell indicate a role for T cells in the development of disease; treatment with anti-CD20 antibodies ameliorates disease |
| PI3K$^{-/-}$ | Lymphocytic infiltration of the lacrimal glands; anti-Ro/SS-A and anti-La/SS-B antibodies | |
| BAFF transgenic | Lymphocytic infiltration of lacrimal and salivary glands; unique population of marginal zone B cells in salivary glands | No anti-Ro/SS-A or anti-SS-B antibodies; also develop lupus manifestations and anti-DNA antibodies and RF |
| IL-14α transgenic | Lymphocytic infiltration of lacrimal and salivary glands; hypergammaglobulinemia; <25% of animals develop anti-Ro/SS-A and anti-La/SS-B antibodies; glandular hyposecretion; mild immune complex–mediated renal disease and lymphocytic interstitial pneumonitis | IL-14 is a growth factor for B cells; mice develop large B cell lymphomas later in life; role for LT-α in the salivary gland inflammation; infiltrate primarily B cells with relatively few $CD4^+$ and $CD8^+$ T cells |
| IL-12 transgenic | Lymphocytic infiltration of lacrimal and salivary glands; anti-La/SS-B antibodies; glandular hyposecretion; increased acinar cell volume | Mice also develop thyroiditis and lung pathology |

*See references 58 and 59 for further details.

BAFF, B cell–activating factor; F, female; ICA69, islet cell antigen 69; Id3, protein inhibitor of DNA binding 3; IFN-γ, interferon-γ; IL-1, interleukin-1; LT-α, lymphotoxin-α; LT-βR, lymphotoxin-β receptor; M, male; M3R, muscarinic receptor subtype 3; NOD, nonobese diabetic; NZB/NZW F1, New Zealand Black × New Zealand White F1 (mouse hybrid); PIK3, phosphoinositide-3-kinase; RF, rheumatoid factor; TCR, T cell receptor; TNF, tumor necrosis factor.

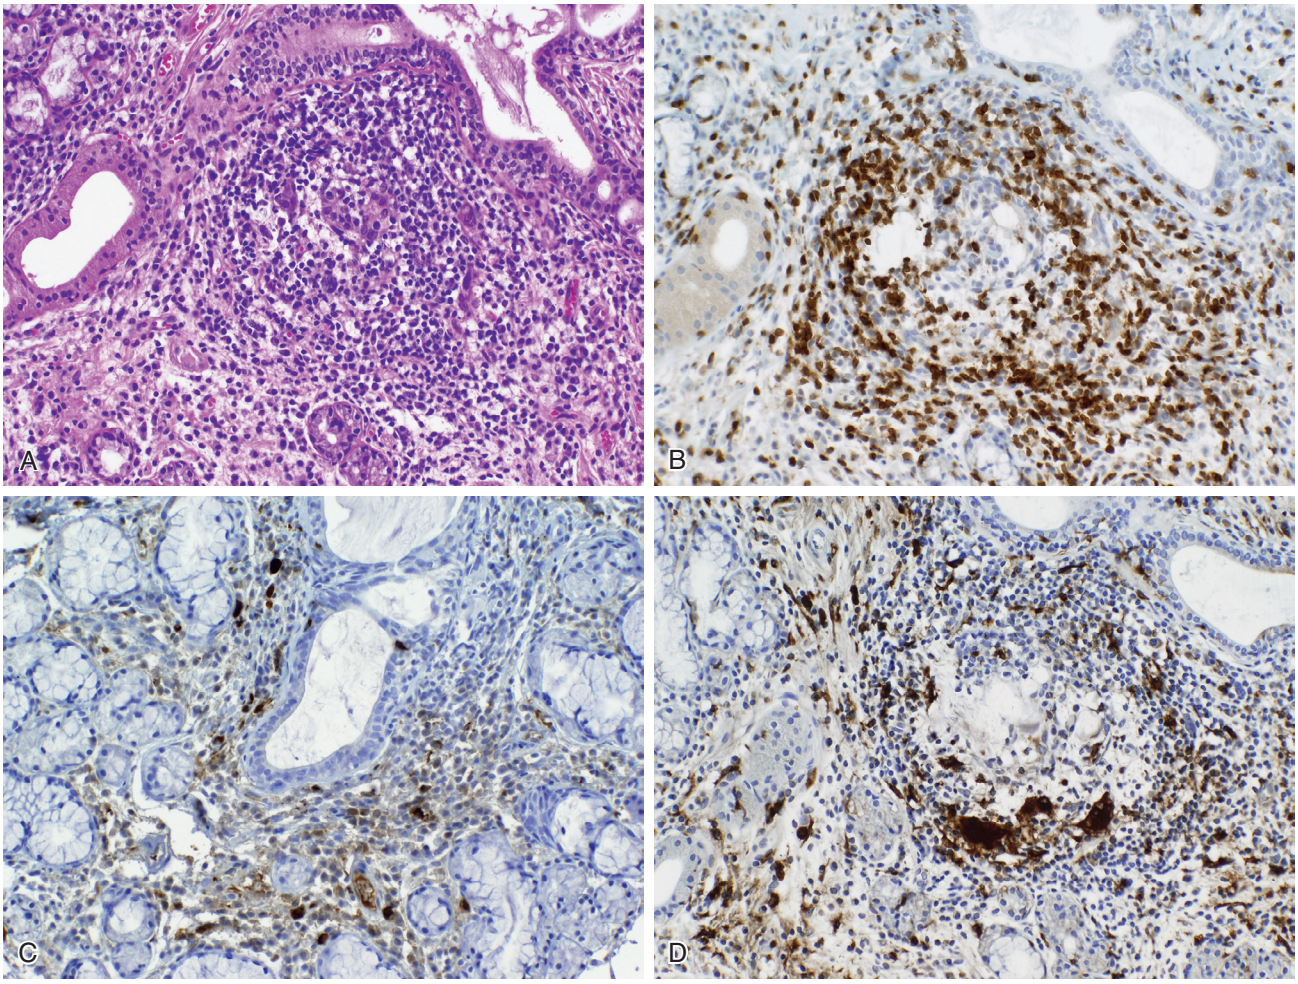

**Figure 73-1** Histopathology of the labial salivary glands in primary Sjögren's syndrome. **A,** Hematoxylin-eosin (20×). **B,** Anti-CD3 staining of T cells (20×). **C,** Anti-CD21 staining of B cells (20×). **D,** Anti-CD68 staining of macrophages (20×). Mononuclear cells aggregate in foci throughout the glands **(A)**. In this biopsy, most of the mononuclear cells are T cells **(B)**, with fewer numbers of B cells **(C)** and macrophages **(D)**.

multiple Vβ families. The proportion of B cells in the infiltrate increases with the severity of the inflammatory lesion.

The infiltrating mononuclear cells tend to coalesce around ducts and blood vessels, and in more severe inflammatory lesions form aggregates organized into GC-like structures. The GC-like structures display well-circumscribed mononuclear cell infiltrates with B and T cell components, Ki-67$^+$ proliferating cells, CD21/CD35$^+$ follicular DC networks, and CD31$^+$ high endothelial venules (HEVs).[67] CXCL13 expression by epithelial cells, HEVs, and within GC-like structures together with the expression of CXCL12 and CCL21 provides a salivary gland microenvironment capable of attracting and retaining B cells.[68-70] The receptor for CXCL13 is CXCR5, which is expressed on the surface of B cells and follicular Th cells. The myeloid DCs and macrophages, the classic antigen-presenting cells, are mostly found in proximity to the ductal epithelium, where they secrete TNF, IL-6, IL-10, IL-12, and IL-18. Minor salivary glands also contain a small number of plasmacytoid DCs, the main producers of the type I IFNs.[71] A robust type 1 IFN signature has been detected both in the salivary glands and peripheral blood of patients with primary Sjögren's syndrome.[71,72] The generation of type 1 IFNs by plasmacytoid DCs is among the first lines of defense against viral infection and is partially dependent on signals through TLR7 and TLR9.

The analysis of T cell cytokines in labial salivary gland biopsies from patients with primary Sjögren's syndrome suggests a predominantly Th1- and Th17-driven response.[73] Studies of the expression of cytokine messenger RNAs (mRNAs) in salivary gland tissue show mainly upregulation of IL-2 and IFN-γ, Th1-specific cytokines, and lesser quantities of IL-4, IL-5, and IL-13, the Th2-specific cytokines. Th17 cells are also found in the minor salivary glands; the salivary gland microenvironment is rich in transforming growth factor (TGF)-β, IL-6, and IL-23, which are cytokines known to promote the development of this subset.[74] In addition, the salivary gland contains FoxP3$^+$ regulatory T cells.[75] These cells typically show suppressive behavior, but as yet they have an uncertain role in regulating the chronic inflammatory lesion.

Several features of primary Sjögren's syndrome implicate B cells in disease mechanisms. B cells are the source of autoantibodies, but they also activate T cells by presenting

antigen peptides, secrete both pro-inflammatory and anti-inflammatory cytokines, and promote the organization of secondary and tertiary lymphoid tissue. The frequent presence of hypergammaglobulinemia, circulating immune complexes, mixed monoclonal immunoglobulin M (IgM) cryoglobulinemia, and serum autoantibodies in patients with primary Sjögren's syndrome provide further evidence that B cells are in a dysregulated state in this disease. Most B cells in the salivary gland tissue exhibit a memory phenotype, express somatically hypermutated immunoglobulin V genes, and show preferential changes in $V_L$ gene usage and the length of CDR3 sequences from $V_H$ gene rearrangements, which are findings characteristic of an antigen-driven response.[76] Salivary gland B cells appear to be responding specifically to antigen, although the site of antigen encounter and activation (salivary gland vs. secondary lymphoid tissue) remains uncertain. GC-like structures found in some of the salivary gland biopsies provide an opportune environment for the selection and differentiation of antigen-driven B cell responses. The distribution of peripheral blood B cell subsets in primary Sjögren's syndrome differs from healthy controls, showing increased proportions of $CD27^-$ (naïve) B cells and decreased proportions of $CD27^+$ (memory) B cells.[77] Among several possibilities, these changes in the peripheral blood may result from abnormal trafficking of $CD27^+$ memory B cells to the target tissues, aberrations in B cell development, or both.

Several intrinsic B cell defects have also been found in patients with primary Sjögren's syndrome, including abnormal retention of preswitch Ig transcripts in circulating postswitch $CD27^+$ memory B cells[78] and enhanced B cell signaling due to altered kinetics of B cell receptor translocation to lipid rafts.[79] Moreover, studies in patients with primary Sjögren's syndrome have shown increased serum and salivary gland tissue levels of B cell–activating factor (BAFF), a B cell prosurvival factor,[80] as well as upregulated salivary gland expression of lymphotoxin (LT)-β mRNA.[81] LT-β is required for the formation of lymph nodes and GCs, whereas the heterodimer LT-α/LT-β can induce the development of ectopic GC-like structures. LT-α in soluble form induces the secretion of IFNs and chemokines, which are elevated in the salivary gland tissue from patients with primary Sjögren's syndrome. Levels of IL-14, another B cell growth factor, also appear to be increased in the serum and saliva of patients with primary Sjögren's syndrome.[82] IL-14 transgenic mice develop a Sjögren's-like phenotype[83] in which the local tissue response is critically dependent on LT-α.[84] Blocking LT-β receptor signaling in nonobese diabetic (NOD) mice ablates the lymphoid organization in the salivary glands and improves their function,[85] further evidence that LTs may play a role in the pathogenesis of Sjögren's syndrome. Finally, abnormal B cell behavior is implied in primary Sjögren's syndrome by the predisposition of this disease toward the development of non-Hodgkin's B cell lymphoma. Interestingly, IL-14 transgenic mice develop large B cell lymphomas later in life.[83]

## Autoantibodies

Anti-Ro/SS-A and anti-La/SS-B antibodies do not appear to have a pathogenic role in disease mechanisms despite their diagnostic and prognostic significance. The stimulating antigen(s) is unknown. An aberrant response to self may be provoked by altered expression of autoantigens. Several models have been proposed to explain the altered expression of autoantigens, including differential expression of protein isoforms, post-translational modification, and abnormal autoantigen presentation via apoptotic blebs, exosomes, or heat shock protein–mediated cross-priming.[86] Ro/SS-A and La/SS-B proteins do in fact show upregulated expression in the vicinity of the immunopathologic lesion[86] where they may induce local immune responses. Saliva from patients with this disease contains anti-Ro/SS-A and anti-La/SS-B antibodies.[87] Although this finding may be the result of local production of autoantibodies, it may also reflect extravasation of proteins from blood vessels into the inflamed tissues.

Among the other autoantibody specificities, those directed against the muscarinic receptor (MR) have attracted the most interest because of their possible role in causing glandular hypofunction. The MR family of receptors is bound by acetylcholine, which mediates the effects of the preganglionic and postganglionic parasympathetic nerve fibers that primarily regulate salivary flow. The muscarinic type 3 receptor (M3R), the target of autoantibodies in primary Sjögren's syndrome, is the subtype that predominantly controls salivary flow. Two lines of evidence support the hypothesis that anti-M3R antibodies reduce exocrine gland function. First, serum immunoglobulins from patients with primary Sjögren's syndrome bind M3R receptors on acinar cell membranes. They also inhibit acetylcholine-evoked $Ca^{2+}$ responses in a salivary gland cell line.[88] This $Ca^{2+}$-sensitive response is tightly regulated through intracellular signaling pathways that open the $Cl^-$ channels on the apical membrane, resulting in an osmotic gradient and movement of water into the duct lumen. Second, passive transfer of the antibody causes glandular hypofunction in NOD mice, an animal model of Sjögren's syndrome.[89] However, the different assays for detecting serum anti-M3R antibodies in patients with primary Sjögren's syndrome have produced inconsistent results. For this reason, it has been difficult to determine the diagnostic sensitivity and specificity of serum anti-M3R antibodies in primary Sjögren's syndrome and the possible relationship of these autoantibodies to glandular hypofunction. Other autoantigens have been identified in patients with primary Sjögren's syndrome and include α-fodrin, poly(ADP)ribose polymerase, carbonic anhydrase, and ICA69 protein. Despite initial enthusiasm for the possible etiologic role of α-fodrin in primary Sjögren's syndrome, recent studies have shown that serum anti–α-fodrin antibodies are not highly specific for this diagnosis.[90] Autoantibodies to carbonic anhydrase, poly(ADP)ribose polymerase, and ICA69 protein occur in only a minority of patients with primary Sjögren's syndrome and therefore do not appear to be important for initiating disease.

## Glandular Epithelium

In primary Sjögren's syndrome, the glandular epithelial cell may also drive the abnormal immune response. In the salivary gland, the mononuclear cells preferentially congregate around ductal epithelium. The epithelial cells show upregulated expression of class I and II HLA

molecules; adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1; CD54), vascular cell adhesion molecule-1 (VCAM-1; CD106) and E-selectin; and costimulatory molecules such as CD80 and CD86[91]; they also produce high levels of cytokine mRNAs for IL-1, IL-6, IL-12, IL-18, and TNF,[92-94] as well as BAFF.[80] Ductal epithelial cells express mRNAs for several different proinflammatory chemokines, including CXCL13, CCL17, CCL21, and CCL22.[95] Cultured salivary gland epithelial cells express functional TLR3 and TLR7 molecules,[96,97] endowing them with a capability to sense pathogens and endogenous molecules produced by injured tissues. Activated epithelial cells are likely drivers of the aberrant innate and adaptive immune responses, not only in the lacrimal and salivary glands, but also in the lungs and kidneys, as well as other extraglandular sites.

At least two models have been proposed to explain the glandular hypofunction in Sjögren's syndrome. In one model, it may be hypothesized that the glandular tissue is destroyed by an immune onslaught perpetuated by persistent exposure to self-antigens or other environmental stimulants (e.g., viral infection), leading to apoptosis of acinar epithelial cells and the irreversible loss of salivary gland function[98] (Figure 73-2A). A weakness of this model is that studies suggest epithelial cells rarely undergo apoptosis in the salivary gland tissue despite the fact they increase expression of mediators of cell death such as Fas, Fas ligand, and Bax (B cell lymphoma 2–associated X protein).[99] Ligand binding to CD40 expressed on epithelial cells in the salivary gland tissue also leads to Fas-mediated cell death by downregulating c-FLIP (cellular FLICE-like inhibitor protein), an inhibitor of Fas-mediated cell death.[100] Because no studies have yet shown that an imbalance truly exists between the rates of glandular proliferation and damage, the relevance of this model to glandular hypofunction is uncertain. It also does not explain why many patients with markedly diminished salivary flow retain substantial amounts of normal-appearing acinar tissue in their salivary glands.[101]

A second model assumes that apoptosis is not a significant factor in the loss of acinar epithelium and, instead, posits that glandular function is inhibited (and not destroyed) by immune-mediated mechanisms (see Figure 73-2B). This model implies a reversibility component to the loss of salivary flow and a pathologic process interrupting M3R activation. Possible mechanisms for such inhibitory effects include a reduction in acetylcholine release, increased breakdown of acetylcholine in the epilemmal space (e.g., acetylcholine must diffuse 100 nm from its release point at the nerve ending to the receptor on the cell), and blockade of M3R by antibodies.[102] Relatively little direct evidence supports any of these mechanisms, except for the experiments showing that anti-M3R antibodies may block receptor function. Nevertheless, it is possible that the cytokine milieu in the inflamed glandular tissue interferes with the mechanisms controlling acinar gland function. In the NOD mouse, for example, impairment of salivary gland secretion does not appear to be readily explained by the destruction of acinar glands.[103] Regardless, the "immune destructive" and "immune inhibited" models are not mutually exclusive and may contribute to glandular hypofunction at various stages of the disease.

## CLINICAL FEATURES

### Keratoconjunctivitis Sicca

Chronic inflammation of the lacrimal glands diminishes secretion of aqueous tears, which if severe, may destroy the conjunctival and bulbar epithelium. Aqueous tear deficiency produces a dry eye, causing symptoms of grittiness or foreign body sensation, burning, photophobia, and eye fatigue. Routine eye examination usually reveals a reduction in the tear flow, as measured by the Schirmer-I test. Additional findings may include the absence of tears in the conjunctival sac and dilated bulbar conjunctival vessels. Thick mucus may also be seen in the inner canthus of the eye. Slit-lamp examination allows for more detailed visualization of the corneal and conjunctival surface. After instillation of lissamine green dye or fluorescein onto the ocular surface, slit-lamp examination may expose devitalized cells or epithelial defects, respectively, signs of corneal and conjunctival damage. Severe dryness may result in corneal abrasion or ulceration.

The anatomy of the tear film informs the differential diagnosis of a dry eye (Table 73-3). The tear film consists of three major layers: the outer lipid layer, the middle aqueous layer, and the inner mucin layer. The middle aqueous layer is diminished in Sjögren's syndrome. Conditions associated with infiltration of the lacrimal glands (e.g., sarcoidosis) and diminished tear flow (e.g., medications, aging, and estrogen deficiency) may also decrease aqueous tear flow. The lipid layer derives from the meibomian glands and traps the aqueous tear film on the eyeball and protects it from rapid evaporation. Meibomian gland dysfunction, or posterior blepharitis, produces dry eyes from rapid evaporation of tears; it may be present with aqueous tear deficiency and be an aggravating factor in patients with keratoconjunctivitis sicca. Meibomian gland dysfunction is often associated with ocular rosacea and seborrheic dermatitis, two conditions encountered often in clinical practice that also lead to symptoms of dry eyes. Lipid degradation resulting from meibomian gland inflammation may produce free fatty acids, which irritate the ocular surface and may cause punctate keratopathy. The mucin layer originates from the goblet cells of the conjunctiva and, if deficient, leads to an uneven distribution of the tear film over the surface of the eye. Vitamin A deficiency and Stevens-Johnson syndrome are examples of conditions associated with an abnormal mucin layer.

### Xerostomia

The changes in the quality and quantity of the saliva are responsible for the signs and symptoms of xerostomia. Although symptoms of dry mouth are relatively common in the general population, they are usually more severe in Sjögren's syndrome and cause incessant difficulties with chewing and swallowing dry food, altered taste (metallic, salty, or bitter), and struggles with prolonged speaking. Patients with xerostomia may have problems wearing dentures. Despite complaints of a dry mouth, many patients will appear to have a normal oral examination because of residual salivary flow. Others with more severe hypofunction will manifest a dry, sticky, or erythematous oral mucosa.
